Introduction to Data Adapters

Data adapters are an integral part of ADO.NET managed providers, which are the set of objects used to communicate between a data source and a dataset. (In addition to adapters, managed providers include connection objects, data reader objects, and command objects.) Adapters are used to exchange data between a data source and a dataset. In many applications, this means reading data from a database into a dataset, and then writing changed data from the dataset back to the database. However, a data adapter can move data between any source and a dataset. For example, there could be an adapter that moves data between a Microsoft Exchange server and a dataset.

> **Note** For more information about data providers, see Using .NET Data Providers to Access Data.

Generally, adapters are configurable to allow you to specify what data to move into and out of the dataset. Often this takes the form of references to SQL statements or stored procedures that are invoked to read or write to a database.

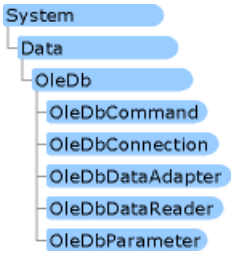
Visual Studio makes these data adapters available for use with databases:

- The OleDbDataAdapter object is suitable for use with any data source exposed by an OLE DB provider.
- The SqlDataAdapter object is specific to SQL Server. Because it does not have to go through an OLE DB layer, it is faster than the **OleDbDataAdapter**. However, it can only be used with SQL Server 7.0 or later.
- The OdbcDataAdapter object is optimized for accessing ODBC data sources.
- The OracleDataAdapter object is optimized for accessing Oracle databases.

> **Note** Data Adapters, Data Connections, Data Commands, and Data Readers are the components that make up a .NET Framework data provider. Microsoft and third-party providers can make available other .NET data providers that can be integrated into Visual Studio. For more information on the different .NET Framework data providers, see .NET Framework Data Providers.

You can create and manipulate adapters using the following portions of the .NET Framework managed-provider namespaces.

OleDb Managed-Provider Namespace



SqlClient Managed-Provider Namespace

Generally, each data adapter exchanges data between a single data-source table and a single DataTable object in the dataset. If the dataset contains multiple data tables, the usual strategy is to have multiple data adapters feeding data to it and writing its data back to individual data-source tables.

When you want to populate a table in a dataset, you call an adapter method that executes an SQL statement or stored procedure. The adapter creates a data reader object (SqlDataReader, OleDbDataReader, OdbcDataReader, or OracleDataReader) to read the data into a dataset.

> **Note** You can read data from the database without having to store it in a dataset, which can be very efficient for situations involving read-only data. For details, see "Read-Only Data" below. You can also execute SQL statements directly without using them to populate a dataset. For details, see Performing Database Operations Directly.

Similarly, when you want to update the database, you invoke an adapter method that calls an appropriate SQL statement or stored procedure to make the actual update in the database.

Data Adapters and Related Tables

An implication of having separate tables in the dataset is that a data adapter typically does not reference SQL commands or stored procedures that join tables. Instead, information from the related tables is read separately into the dataset by different adapters. Then a **DataRelation** object is used to manage constraints between the dataset tables (such as cascading updates) and to allow you to navigate between related master and child records.

For example, imagine that you are working with two related tables in the Northwind database, Customers and Orders. Rather than specifying a join to combine both tables into a single result set, you would most commonly define two adapters, one to populate a Customers table in the dataset and a second adapter to read Order records into a different dataset table. The individual adapters would probably include selection criteria to limit the number of records in the data tables.

In the dataset you would also define a **DataRelation** object specifying that order records are related to customer records by the CustomerID field. You can still manage the tables individually, which would not be possible if you had joined tables before fetching records from the data source. For situations where you wanted to work with related records, you can invoke properties and methods of the **DataRelation** object.

For more information about data relations, see Relationships in ADO.NET Datasets.

Connection Objects

A data adapter needs an open connection to a data source to read and write data. Therefore, an adapter uses connection objects (SqlConnection, OleDbConnection, OdbcConnection, or OracleConnection)to communicate with a data source. (The adapter can contain up to four connection references, one for each type of action it can perform: Select, Update, Insert, and Delete.)

The following table lists connection objects in the Data tab of the Toolbox:

Connection Object	Description
SqlConnection	A connection to a SQL Server 7.0 or later database.
OleDbConnection	A connection to any OLE DB data source.
OdbcConnection	A connection to an ODBC data source.
OracleConnection	A connection to an Oracle database.

In all cases, the connection object represents a unique session within the data source. All connection objects provide properties to establish and modify connection details (such as user ID and password, and connection-timeout setting). They also provide methods to begin, commit, and roll back database transactions. For details about connection objects, see Connecting to Data Sources with ADO.NET.

> **Security Note** Storing connection-string details (such as the server name, user name, and password) can have implications for the security of your application. Using Windows integrated security is a more secure way to control access to a database. For more information, see Database Security.

ADO.NET Command Objects

Using an adapter, you can read, add, update, and delete records in a data source. To allow you to specify how each of these operations should occur, an adapter supports the following four properties:

- **SelectCommand** – reference to a command (SQL statement or stored procedure name) that retrieves rows from the data store.
- **InsertCommand** – reference to a command for inserting rows into the data store.
- **UpdateCommand** – reference to a command for modifying rows in the data store.
- **DeleteCommand** – reference to a command for deleting rows from the data store.

The properties are themselves objects — they are instances of the SqlCommand, OleDbCommand, OdbcCommand, or OracleCommand class. The objects support a **CommandText** property containing a reference to an SQL statement or stored procedure.

> **Note** The command class must match the connection class. For example, if you are using a **SqlConnection** object to communicate with a SQL Server, you must also use commands that derive from the **SqlCommand** class.

Although you can explicitly set the text of a command object, you do not always need to; in many situations, Visual Studio will generate the SQL statements needed. In addition, the adapter can automatically generate appropriate SQL statements at run time if the **UpdateCommand**, **InsertCommand**, or **DeleteCommand** objects are not specified. For details, see Automatically Generated Commands.

However, you can manipulate command objects at design time and run time in order to have more direct control over how the commands are executed. For example, you can create or modify the command associated with a **SelectCommand** object just before it is executed.

You can also execute commands yourself, independently of the data adapter. This allows you to pass arbitrary SQL commands through the data adapter, such as those used to define or modify database definitions. You can also call stored procedures directly that do not return record sets — for example, a stored procedure that validates a user entry against a database. For details, see Executing a Command.

> **Security Note** When using data commands with a CommandType property set to **Text**, carefully check information that is sent from a client before passing it to your database. Malicious users might try to send (inject) modified or additional SQL statements in an effort to gain unauthorized access or to damage the database. Before you transfer user input to a database, you should always verify that the information is valid; it is a best practice to always use parameterized queries or stored procedures when possible. For more information, see Scripting Exploits.

Command Parameters

The commands in a data adapter are usually parameter-driven. The command for the **SelectCommand** property, for example, often has a parameter in its WHERE clause so you can specify at run time what records to get from the database. The other commands use parameters that allow you to pass at run time the data to write into a record and what record in the database to update. For more information about how parameters are used in data adapters, see Parameters in Data-Adapter Commands.

Reading and Updating with Data Adapters

The primary purpose of the data adapter is to communicate data between a data store and a dataset. The adapter supports specific methods to move the data back and forth between the two.

> **Note** If you just want to read data (not update it), you do not have to store it in a dataset. Instead, you can read directly out of the database and into an application. For details, see "Read-Only Data" below.

You can use a data adapter to perform the following operations:

- Retrieve rows from a data store into corresponding data tables within the dataset.

  To retrieve rows into a dataset, use the **Fill** method on a data adapter object (SqlDataAdapter, OleDbDataAdapter, OdbcDataAdapter, or OracleDataAdapter). When you invoke the **Fill** method, it transmits an SQL SELECT statement to the data store.

- Transmit changes made to a dataset table to the corresponding data store.

  To transmit a dataset table of the dataset to the data store, use the adapter's **Update** method. When you invoke the method, it executes whatever SQL INSERT, UPDATE or DELETE statements are needed, depending on whether the affected record is new, changed, or deleted.

  For details about how updates are performed using data adapters, see Dataset Updates in Visual Studio .NET.

Read-Only Data

If your program needs to perform a sequential, read-only pass through a query result, you can use a data reader object in place of filling a dataset. A data reader object fetches the data from the data source and passes it through directly to your application. Typically, data reader objects are used for read-only, forward-only access to the data at times when you do not need to cache data in a dataset. (The data adapter itself uses a data reader object to populate a dataset.) An example is a Web Forms page that displays database information; because the Web Forms page is recreated with each roundtrip, it is often not useful to store the data in a dataset.

Visual Studio supplies four data reader objects, a SqlDataReader, OleDbDataReader, OdbcDataReader, and OracleDataReader. For details about using the data reader object for efficient read-only access, see Executing a Data Command That Returns a Result Set.

Table Mappings

By default, when you use Visual Studio tools to generate a dataset from database tables, the names of the tables and columns are the same in the dataset as in the database. However, you might find this impractical. For example, you might find the names used in the database too terse or verbose; or the names might be in a foreign language. If you are working with an existing schema, you might also find that the names defined in the schema do not match those used in your database.

Therefore, the names in the database and dataset do not have to match. Instead, you can create new table and column names in the dataset command, and then map those to the names used in the database. Adapters use the TableMappings collection to

maintain the correspondence between structures of the dataset (data tables and data columns) and structures of the data store (tables and columns). For details about table mappings, see Table Mapping in Data Adapters.

Mapping Data-Source Columns to Dataset Data-Table Columns

Parameters in Data-Adapter Commands

A data adapter's commands — those defined in the **CommandText** property of the **SelectCommand**, **InsertCommand**, **UpdateCommand**, and **DeleteCommand** objects — often involve parameters. At run time, parameters are used to pass values to the SQL statements or stored procedures represented by the commands.

Parameters are used in two contexts:

- Selection parameters - in production applications, you frequently fetch only a subset of the data in a database. To do so, you use an SQL statement or stored procedure that includes a WHERE clause with a parameter for selection criteria that you get at run time. In addition, when you update or delete records, you use a WHERE clause that pinpoints the record or records to be changed. The values used in the WHERE clause are usually derived at run time.
- Update parameters - when you update an existing record or insert a new one, the values for the columns in the changed or new record are established at run time. In addition, values used during optimistic concurrency checking are established using parameters.

> **Note** For Oracle, when using named parameters in an SQL statement or stored procedure, you must precede the parameter name with a colon (:). However, when referring to a named parameter elsewhere in your code (for example, when calling Add), do not precede the named parameter with a colon (:). The data provider supplies the colon automatically. For more information, see OracleParameter Class.

Selection Parameters

When selecting records to fill a dataset, you often include one or more parameters in the WHERE clause so you can specify at run time which records to fetch. For example, users might search a book database for a specific title keyword that they type into a Web page. To allow that, you might specify an SQL statement like the following as the **CommandText** property of a **SelectCommand**. Parameters are indicated either with a placeholder (a question mark) or with a named parameter variable. Parameters for queries involving **OleDbCommand and OdbcCommand** objects use question marks; queries that use **SqlCommand** objects use named parameters that begin with an @ symbol, whereas **OracleCommand** objects use named parameters that begin with a colon (:).

A query that uses placeholders might look like the following:

```
SELECT BookId, Title, Author, Price from BOOKS
WHERE (Title LIKE ?)
```

A query that uses **SqlCommand** named parameters might look like the following:

```
SELECT BookId, Title, Author, Price from BOOKS
WHERE (Title LIKE @title)
```

A query that uses **OracleCommand** named parameters might look like the following:

```
SELECT BookId, Title, Author, Price from BOOKS
WHERE (Title LIKE :title)
```

In your application, you prompt the user for a title keyword. You then set the parameter value and run the command.

> **Note** Occasionally, you might want to get the entire contents of a database table — for example, if you are setting up a lookup table — but generally, you want to fetch only the data you need in order to keep your application efficient.

In Visual Studio you can build SQL statements with parameters using the Query Builder. If you drag elements from Server Explorer, Visual Studio can configure parameters in some cases but not all, and you will need to complete the configuration manually.

Update Parameters

Whether or not an adapter's **SelectCommand** object contains a parameterized command, the commands for the **UpdateCommand**, **InsertCommand**, and **DeleteCommand** properties always do.

The commands for the **UpdateCommand** and **InsertCommand** properties need parameters for every column in the database to be updated. In addition, the **UpdateCommand** and **DeleteCommand** statements require a parameterized WHERE clause that

identifies the record to be updated, similar to the way the **SelectCommand** object is often configured.

Imagine an application where users can buy books. As users shop, they maintain a shopping cart, which is implemented as a data table. In the ShoppingCart table, users maintain a record for each book they want to buy, with the book ID and customer ID together acting as the key to the shopping cart record.

When users add a book to their shopping cart, the application might invoke an SQL INSERT statement. In the adapter, the statement's syntax might look like the following:

```
INSERT INTO ShoppingCart
   (BookId, CustId, Quantity)
Values (?, ?, ?)
```

The three question marks represent parameter placeholders that will be filled in at run time with values for the customer ID, book ID, and quantity. If you are using named parameters, the same query might look like this:

```
INSERT INTO ShoppingCart
   (BookId, CustId, Quantity)
Values (@bookid, @custid, @quantity)
```

If the user decides to change something about an item in the shopping cart — for example, by changing the quantity — the application might invoke an SQL UPDATE statement. The syntax of the statement might be as follows:

```
UPDATE ShoppingCart
   SET (BookId = ?, CustId = ?, Quantity = ?)
WHERE (BookId = ? AND CustId = ?)
```

Or if you are using named parameters, it might be as follows:

```
UPDATE ShoppingCart
   SET (BookId = @bookid, CustId = @custid, Quantity = @quantity)
WHERE (BookId = @bookid AND CustId = @custid)
```

In this statement, the parameters in the SET clause are filled in with updated values for the changed record. The parameters in the WHERE clause identify which record to update and are filled in with the original values from the record.

A user might also remove an item from the shopping cart. In that case, the application might invoke an SQL DELETE statement with syntax such as the following, if you are using parameter placeholders:

```
DELETE FROM ShoppingCart
WHERE (BookId = ? AND CustId = ?)
```

Or the following if you are using named parameters:

```
DELETE FROM ShoppingCart
WHERE (BookId = @bookid AND CustId = @custid)
```

The Parameters Collection and Parameter Objects

To allow you to pass parameter values at run time, each of the four command objects for a data adapter supports a **Parameters** property. The property contains a collection of individual parameter objects that correspond one-to-one with the placeholders in a statement.

The following table shows the corresponding parameter collection for each data adapter:

Data adapter	Parameter collection
SqlDataAdapter	SqlParameterCollection
OleDbDataAdapter	OleDbParameterCollection
OdbcDataAdapter	OdbcParameterCollection
OracleDataAdapter	OracleParameterCollection

Note For Oracle, when using named parameters in an SQL statement or stored procedure, you must precede the parameter name with a colon (:). However, when referring to a named parameter elsewhere in your code (for example, when calling Add), do not precede the named parameter with a colon (:). The .NET Framework Data Provider for Oracle supplies the colon automatically.

By using the parameters collection, you save yourself the trouble of having to manually construct a SQL command as a string with run-time values; in addition, you get the benefit of type checking in your parameters.

If you use the Data Adapter Configuration Wizard to configure the adapter, the parameters collection is set up and configured automatically for all four adapter commands. If you drag elements from Server Explorer onto the form or component, Visual Studio can perform the following configurations:

- If you drag a table or some columns onto the designer, Visual Studio generates a **SelectCommand** object (specifically, an SQL SELECT statement) with no parameters, and parameterized **UpdateCommand**, **InsertCommand**, and **DeleteCommand** objects. If you want the **SelectCommand** object statement to have parameters, you must configure them manually.
- If you drag a stored procedure onto the designer, Visual Studio generates a **SelectCommand** object, with parameters as required by the stored procedure. However, if you need them, you must configure the **UpdateCommand**, **InsertCommand**, and **DeleteCommand** objects yourself, along with their parameters.

Generally speaking, if you want to create parameterized queries for the adapter, you should use the Data Adapter Configuration Wizard. However, should you need to, you can configure parameters manually using the Properties window.

Structure of the Parameters Collection

The items in a command's parameters collection correspond one-to-one to parameters required for the corresponding command object. If the command object is an SQL statement, the items in the collection correspond to the placeholders (question marks) in the statement. The following UPDATE statement requires a collection of five parameter items:

```
UPDATE ShoppingCart
   SET (BookId = ?, CustId = ?, Quantity = ?)
WHERE (BookId = ? AND CustId = ?)
```

Here is the same statement with named parameters:

```
UPDATE ShoppingCart
   SET (BookId = @bookid, CustId = @custid, Quantity = @quantity)
WHERE (BookId = @bookid AND CustId = @custid)
```

If the command object references a stored procedure, the number of parameter items in the collection is determined by the procedure itself. The parameters might not correspond exactly to the placeholders in an SQL statement.

In stored procedures, parameters can also be named. In that case, the position of a parameter in the collection is not important. Instead, each parameter item in the collection has a **ParameterName** property that is used to match it to the corresponding parameter in the stored procedure.

If you are configuring the parameters collection manually, you must understand exactly which parameters the stored procedure requires. Many stored procedures return a value; if so, the value is passed back to your application in the parameters collection, so you must allow for that. In addition, some stored procedures include multiple SQL statements, and you must be sure that the parameters collection reflects all the values passed to all statements in the procedure.

If parameters are not named (as in stored procedures), the items in the collection map positionally to the parameters required by the command. If the command is a stored procedure and it returns a value, the first item in the collection (item zero) is reserved for this return value.

You can therefore reference individual parameter objects by index position in the collection. However, parameter objects also support a **ParameterName** property that provides a way to reference parameters independently of their order. For example, the following two statements might be equivalent (assuming that the second parameter in the collection is named `Title_Keyword`):

```
' Visual Basic
' Encloses the keyword in SQL wildcard characters.
titleKeyword = "%" & txtTitleKeyword.Text & "%"
OleDbDataAdapter1.SelectCommand.Parameters(1).Value = titleKeyword
OleDbDataAdapter1.SelectCommand.Parameters("Title_Keyword").Value = titleKeyword
```

```
// C#
// Encloses the keyword in SQL wildcard characters.
string titleKeyword = "%" + txtTitleKeyword.Text + "%";
this.OleDbDataAdapter1.SelectCommand.Parameters[1].Value = titleKeyword;
this.OleDbDataAdapter1.SelectCommand.Parameters["Title_Keyword"].Value = titleKeyword;
```

Using a parameter name is generally a much better programming practice than referencing parameters by index value, because it reduces the need for maintenance if the number of parameters changes and frees you from having to remember whether a stored procedure returns a value. There is slight additional overhead in referencing a parameter by name rather than index value, but this can be offset by ease of programming and by application maintainability.

Establishing Parameter Values

There are two ways that you can establish the value of a parameter:

- By setting the parameter's **Value** property explicitly.
- By mapping parameters to columns in a dataset table, so that the values can be extracted from data rows when needed.

You set the parameter value explicitly when you are filling a dataset or calling a command — that is, for selection parameters. For example, in the example above of searching for books, the application might have a text box where users enter a title keyword. You would then explicitly set the value of the parameter to the text of the text box before calling the adapter's **Fill** method. Code to do this might look like the following, which establishes the contents of a text box as a parameter before filling a dataset.

```
' Visual Basic
' Encloses the keyword in SQL wildcard characters.
titleKeyword = "%" & txtTitleKeyword.Text & "%"
OleDbDataAdapter1.SelectCommand.Parameters("Title_Keyword").Value = titleKeyword
OleDbDataAdapter1.Fill(dsAuthors1)

// C#
// Encloses the keyword in SQL wildcard characters.
titleKeyword = "%" + txtTitleKeyword.Text + "%";
this.OleDbDataAdapter1.SelectCommand.Parameters["Title_Keyword"].Value = titleKeyword;
this.OleDbDataAdapter1.Fill(dsAuthors1);
```

Mapped parameter values are used during updates. When you call an adapter's **Update** method, the method walks through the records in a dataset table, individually making the appropriate update (update, insert, delete) for each record. In that case, the parameter values are already available as columns in the dataset records. For example, when the update process gets to a new record in the dataset table — a record for which it must call an INSERT statement in the database — the values for the INSERT statement's VALUE clause can be read directly out of the record.

These are typical scenarios, but not the only ones. Stored procedures sometimes return data using out parameters or via the procedure's return value. If so, the returned values should be mapped to columns in a dataset table.

It is possible to set update parameters explicitly as well. The adapter supports a **RowUpdating** event that is called each time a row is being updated. You can create a handler for this event and set parameter values there. This gives you very precise control over parameter values, and allows you to perform processes such as creating parameter values dynamically before they are written to a database record.

Table Mapping in Data Adapters

When a data adapter reads data from a data source, it determines where to put the data in the corresponding dataset table (or tables) using a table mapping. The mapping links the names of columns in the source with those in the dataset table. For example, information from a column called `au_id` in the data source might belong in a column called `author_id_number` in the dataset table.

By default, when you use Visual Studio tools to generate a dataset from information in a data source, the dataset elements have the same names as they have in the source. However, there are times when the names in the data source and the data set will not match:

- The dataset was created from an existing schema that uses different names.
- You want to change data element names in the dataset for convenience, readability, translation to or from a foreign language, or another reason.
- You want to control the names of typed data members when you generate a dataset from the adapter.

Table Mappings Structure

Table mappings are established using the adapter's TableMappings property, which is a collection of items of type DataTableMapping. There is one **DataTableMapping** object for each set of tables being mapped. Normally there is just one such item, because adapters are normally associated only with a single source table and a single dataset table. (However, a stored procedure can return multiple row sets; if so, the second and subsequent tables are mapped using the second and subsequent mappings in the **TableMappings** collection.)

Each mapping item in turn contains properties to identify the data-source table, the dataset table, and a **ColumnMappings** property containing items that represent the actual mappings.

Table Mapping in Action

When you call a data adapter's **Fill** method, the adapter goes through the following process to determine where in the dataset to write the data:

1. The adapter looks up each source column name in the **TableMappings** object.
2. When it finds the source column name, it gets the matching (mapped) name for the corresponding column in the dataset table.
3. Using the name it got from Step 2, the adapter writes the data from the source column to the corresponding dataset column.

There are a variety of conditions that can prevent the adapter from following the process outlined above. The two primary ones are:

- No mapping can be found for a source column. This might be because there is nothing defined for the **TableMappings** property, or because a specific column is not mapped.
- The column to be written is not defined in the dataset's schema, whether or not it is mapped in the **TableMappings** property.

The adapter supports two properties that allow you specify what should happen when either of these situations occurs. The situations are not necessarily error conditions, because the adapter can still fill the dataset even if either situation occurs.

The MissingMappingAction property allows you to specify what action the adapter should take if the mapping is missing. Possible settings are:

- **Passthrough** - the adapter attempts to load the column into a dataset column of the same name. If there is no dataset column of that name, the behavior depends on the **MissingSchemaAction** setting (see below).
- **Ignore** - columns that are not mapped properly are not loaded into the dataset.
- **Error** - raises an error.

The MissingSchemaAction property allows you to specify what should happen when the adapter tries to write data to a column that is not defined in the dataset's schema. Possible values are:

- **Add** - the table or column is added to the schema and to the dataset.
- **AddWithKey** - the table or column is added to the dataset and schema along with information about the primary key.
- **Ignore** - the table or column not represented in the dataset schema is not added to the dataset.

- **Error** - the adapter raises an error.

You generally set both properties in conjunction to accommodate your application's specific needs. Setting the **MissingMappingAction** property to **Passthrough** and the **MissingSchemaAction** to **Add** has the effect of automatically duplicating the table and column names from the source in the dataset.

Conversely, you might specify error checking in applications where the dataset schema is strictly defined. In such a case, getting data from a source without a clearly defined target column in the dataset might constitute violation of a business rule or other error.

You specify **Ignore** when you want to ensure that the only data loaded into the dataset is that which you have explicitly defined in the schema or mapped in the **TableMappings** property. This is useful if the adapter calls a stored procedure or SQL statement that returns more columns than you need in the dataset.

Creating Data Adapters

Data adapters define the means by which you can get information from one or more tables in the data source into a dataset and back again. For an overview, see Introduction to Data Adapters.

In Visual Studio there are a number of ways you can create and configure data adapters: using Server Explorer, a wizard, "manually" (configuring it with the Properties window), and in code. The topics listed below provide information on each method.

In This Section

Creating Data Adapters Using Server Explorer
Explains how you can drag database elements onto a form or component and generate the adapter automatically.
Creating Data Adapters Using a Wizard
Explains how the Data Adapter Configuration Wizard prompts you for all the information required to configure the data adapter (including parameters) and, if necessary, create a connection.
Creating and Configuring Data Adapters Manually
Explains how to drag a data adapter from the Toolbox, and then configure it yourself using the Properties window.
Populating a DataSet from a DataAdapter

Creating Data Adapters Using Server Explorer

This procedure describes creating data adapters from Server Explorer. Often, you will want to make configuration changes to the adapter after creating it. For details, see Creating and Configuring Data Adapters Manually.

To create a data adapter with Server Explorer

1. Open the form or component in the appropriate designer and then open Server Explorer. For details, see Accessing and Initializing Server Explorer.
2. If the connection you need does not already exist, create it. For details, see Adding New Data Connections in Server Explorer.

   Security Note Storing connection-string details (such as the server name, user name, and password) can have implications for the security of your application. Using Windows integrated security is a more secure way to control access to a database. For more information, see Database Security.

3. Open the connection node and then expand any of the element nodes (**Tables**, **Stored Procedures**, **Views**, or **Functions**). If you are working with tables, expand the table name node to display the table columns.

   Note If you are working with stored procedures, you will need to manually configure the **UpdateCommand**, **InsertCommand**, and **DeleteCommand** properties of the adapter after creating it. For details, see Creating and Configuring Data Adapters Manually.

4. Select one or more columns (under **Table**) or a stored procedure, and then drag the selection onto the designer.

   Note You can drag the table name to the designer instead of selecting and dragging individual columns. Doing so results in an SQL SELECT * FROM tablename query. Selecting individual columns is generally more efficient, because you limit the amount of data that is transferred between the database and the dataset.

   When you drop the selection onto the designer, Visual Studio creates an instance of a connection object for that data source (if there is not already one there) and a data adapter object.

   If you dragged a table or individual columns onto the designer, the adapter is configured for both reading and updating data. If you dragged a stored procedure onto the designer, the adapter is configured for reading data. For details about configuring the commands for updating, see Creating and Configuring Data Adapters Manually.

5. If you want to see how the data adapter will fill a dataset, preview the results. For details, see Previewing Data-Adapter Results.

   At this point, you can create a dataset based on information in the adapter. For details, see Creating Typed Datasets with the Component Designer.

Dragging data elements from Server Explorer is easy, but does not give you the opportunity to create a parameterized query or to create new stored procedures to access data. For that, you can use the Data Adapter Configuration Wizard. For details, see Creating Data Adapters Using a Wizard.

Creating Data Adapters Using a Wizard

The Data Adapter Configuration Wizard provides the simplest and most flexible way to create data adapters. For details, see Data Adapter Configuration Wizard.

To create a data adapter using the Data Adapter Configuration Wizard

1. Open the form or component you are creating in the appropriate designer.
2. From the **Data** Tab of the Toolbox, drag an OleDbDataAdapter, SqlDataAdapter, OdbcDataAdapter, or OracleDataAdapter object onto the design surface.

   The designer adds an instance of the adapter to the form or component and launches the Data Adapter Configuration Wizard.

3. In the wizard, do the following:
   a. In the second page, create or choose a connection. For more information about creating connections, see Creating ADO.NET Connection Objects.

      Security Note Storing connection-string details (such as the server name, user name, and password) can have implications for the security of your application. Using Windows Integrated Security is a more secure way to control access to a database. For more information, see Database Security.

   b. In the third page, specify whether the adapter should use SQL statements or stored procedures to read and write data. Choose one of the options listed in the following table.

Option	Description
Use SQL statement	You will define an SQL SELECT statement that the adapter will use to populate a table in the dataset. Based on your SELECT statement, the wizard will also generate UPDATE, INSERT, and DELETE statements for updating the data source.
Use newly created stored procedures	You specify a SELECT statement, and the wizard creates stored procedures from the statement to read and update the data source. If the provider does not support this option, it is grayed out.
Use existing stored procedures	You will specify existing stored procedures that the adapter will use to read and update the data source.

   The choice you make determines what appears on the following pane.

   c. In the fourth page, either create the SELECT statement or select the existing stored procedures. For assistance building the SQL statement, click **SQL Builder** to launch the **Query Builder**.

      Note You can create a query with a parameter placeholders in the WHERE clause, which will be filled with information you gather at run time. For details, see Parameters in Data-Adapter Commands.

   When you have finished the wizard, it generates an instance of a connection object with the information you specified in the second page.

4. If you want to change the name of the adapter and connection, select them individually in the designer and give them each a new name in the Properties window.
5. If you want to see what data the adapter will fill into the dataset, you can preview it. For details, see Previewing Data-Adapter Results.

You can also create and configure an adapter manually. To do so, you must already have a connection object available. Part of configuring the data adapter involves establishing table mappings between tables in the data source and the dataset. For details, see Creating and Configuring Data Adapters Manually.

Creating and Configuring Data Adapters Manually

You can create data adapters "manually" — that is, without using a wizard. No matter how you have created the adapter, you can always make configuration changes to it.

To create a data adapter manually

1. Make sure a connection object is available to the form or component that you are working with. For details about adding a standalone connection, see Creating ADO.NET Connection Objects.
2. From the **Data** Tab of the Toolbox, drag an OleDbDataAdapter, SqlDataAdapter, OdbcDataAdapter, or OracleDataAdapter object onto the design surface.

   The designer adds an instance of the adapter to the form or component and launches the Data Adapter Configuration Wizard.

3. Close the wizard.

To configure a data adapter manually

1. Select the adapter, and then in the Properties window, configure the commands used to read and update data. You must configure the **SelectCommand** object. If the adapter will be used to update a data source, you must also configure the **UpdateCommand**, **DeleteCommand**, and **InsertCommand** objects.

   For each command object, set the following properties.

Property	Description
ActiveConnection	Set to reference a connection object. You can create a connection object from the **ActiveConnection** property in the Properties window. Typically, each command object will reference the same connection object, but you have the option of using different connections for each command if your application requires it.
CommandText	Either the text of an SQL statement or the name of a stored procedure. For some providers, you can include multiple statements or stored procedure names in the **CommandText** property, delimited with semicolons (;). The statements or procedures are executed sequentially. This is useful for situations such as issuing a SELECT statement after an update or INSERT statement in order to get back refreshed records and any auto-generated values (such as default or auto-increment values). Not all providers support this facility. For details about updating from datasets, see Dataset Updates in Visual Studio .NET.
CommandType	A value indicating how the value of the **CommandText** property should be interpreted: • **Text** - the command is an SQL statement. • **StoredProcedure** - the command is a reference to a stored procedure. • **TableDirect** - the text is not a command, but the name of a table.
Parameters	A collection of objects of type **Parameter** that you configure to pass values to the command. In the **SelectCommand** object, you create a parameters collection only if the command includes a parameter placeholder. **UpdateCommand**, **InsertCommand**, and **DeleteCommand** objects always require parameters. For details, see Configuring Parameters for Data Adapters.

2. If you do not want the same column names in the data source and dataset, change the mappings. The default value for the **MissingMappingAction** property (Passthrough) will generate the same names in the data source and the dataset automatically. For details, see Mapping Data-Source Columns to Dataset Data-Table Columns.
3. From the **Data** menu, choose **Generate DataSet**.

   Tip If you do not see the **Data** menu, click anywhere in the form or component designer; the menu only appears if the designer has the focus.

4. If you want to see how the data adapter will fill a dataset, preview the results. For details, see Previewing Data-Adapter Results.

Configuring Parameters for Data Adapters

Under most circumstances, a data adapter's **Command** objects (**SelectCommand**, **InsertCommand**, **UpdateCommand**, and **DeleteCommand**) reference SQL statements or stored procedures that require parameters. If you have used the Data Adapter Configuration Wizard to create the adapter, then the parameters for these commands are configured for you automatically. However, you might want to configure parameters manually or make small changes to an existing parameters collection.

> **Tip** To configure parameters after making changes to the SQL statement for a command, you can choose the **Regenerate parameters collection for this command** option in the Query Builder.

To configure parameters for a data adapter

1. Create a data adapter. For details, see Creating Data Adapters.
2. In the form or component designer, select the data adapter and then open the Properties window.
3. Expand the command object for which you want to configure parameters (for example, the **UpdateCommand**) and then in the **Parameters** property, click the ellipsis button (...) to open the **Parameter Collection Editor** window.
4. To create a new parameter object, click **Add**.
5. Place the new parameter at the correct index location in the collection for that parameter by clicking the arrows under **Sort** to move it.
6. To set parameter properties, select the parameter in the **Members** list, and then use the property grid on the right-hand side. The following table lists properties that you typically set.

Property	Description
SourceColumn	The name of a column in a dataset table from which the parameter value will be read. This property is used with parameters that fill values in an UPDATE, INSERT, or DELETE statement (or equivalent stored procedures).
SourceVersion	If the parameter value is being derived via the **SourceColumn** property, **SourceVersion** specifies which version of a dataset record should be used as the parameter value source: • **Original** - the value of the column as it was read from the database. You use this option when you need the value of a column before it has changed. An example is when a primary key is changing but you need the old key to find the record in the database. • **Current** - the value of the column after a record has been updated. This is usually the value to be written to the database. • **Default** - the value to which a column is set if no value is explicitly supplied. For details about different versions of records in the dataset, see Dataset Updates in Visual Studio .NET.
Value	An explicit value to set for the parameter. This property is often set at run time rather than statically at design time. The **Value** property takes precedence over the **SourceColumn** property if both are set.
NamedParameter	An Boolean value indicating whether the parameter corresponds to a variable (typically with the format @*parametername*) or to a placeholder (typically a question mark). If you are working with a **SqlConnection** object and are using named parameters, set this to **true**.
DBType, Precision, Scale, Size	Information about the native data type (in the data store) of the parameter value. The parameter value is converted into or out of the type you specify.
Direction	A specification for whether the parameter value is being passed to the command or back: • **Input** - the value is being passed to the command. This is the default. • **Output** - the value is being passed back from a stored procedure. (Not applicable for SQL statements.) • **InputOutput** - the value is passed to a stored procedure and passed back, usually with a modified value. • **ReturnValue** - the value is an explicit return value. By default, the returned value is the first item (index value zero) in the parameters collection.
Parameter Name	A name by which you can refer to the parameter in the collection, instead of referencing it by its index value. Although not required, a parameter name is recommended for ease of maintenance.

7. Click **OK** to close the **Parameter Collection Editor** window.
8. Repeat Steps 3 through 7 to configure parameters for other command objects.

Mapping Data-Source Columns to Dataset Data-Table Columns

Creating a mapping in a data adapter allows you to establish a correspondence between columns in the data source and columns in a dataset table. For details, see Table Mapping in Data Adapters.

To map data-source columns to a dataset table

1. Create a data adapter. For details, see Creating Data Adapters.
2. In a form or component designer, select the data adapter and open the Properties window.
3. Next to the **TableMappings** property, click the ellipsis button (...).

   The **Mappings** dialog box opens.

4. If you want to map column names from the data source to an existing dataset, check **Use a Dataset to suggest table and column names**, and then select a dataset from the **Dataset** list.

   The tables available in that dataset are listed in the **Dataset table** list, and the columns of the first table in the dataset are filled into the right-hand side of the **Column mappings** grid.

   > **Note** Choosing a dataset is a convenience that allows the **Mappings** dialog box to establish defaults for the dataset columns to map to. The dataset is not part of the information maintained for the mappings in the adapter. Moreover, you might use the same mappings with more than one dataset.

5. Under **Source table**, select the table in the data source to map. If there is only one table in the dataset, the default value is **Table**.
6. Under **Dataset table**, select the table in the dataset to map. If you selected a dataset to map to in Step 3, a name will already be filled in. (By default, the first table in the dataset is referred to as **Table**.)

   Based on your choices (or the defaults), values in the **Source Columns** and **Dataset Columns** lists are filled in. The grid indicates how mapping will be performed: each column in the left-hand column will be matched to the corresponding column in the right-hand column.

7. Adjust the mappings as needed. This can include:

   - Selecting different columns in either the source or dataset column lists to change which columns map to which.
   - Removing columns from the mapping. You might do this if the adapter is returning more columns from the data source than what you need.
   - Adding columns. You might do this if you know that columns will exist at run time that are not represented at design time, or if you deleted a column and now want it back, or if you refined the adapter's query and now need to adjust the mappings.

8. When you have finished adjusting the mappings, click **OK**.
9. If you want to specify how to handle possible error conditions, in the Properties window, select options for the **MissingMappingAction** and **MissingSchemaAction** properties. The following table lists some common settings and their effect.

MissingMappingAction	**MissingSchemaAction**	**Effect**
Passthrough	**Add** or **AddWithKey**	If a column exists in the source but not in the schema and there is no mapping for it, the column is created when the dataset is filled. This is the default setting, and is useful when you simply want to copy all the columns available in the source to the dataset.
Ignore	**Ignore**	If the column is not defined in the dataset schema, or if there is no mapping for it, information is not copied from the source to the dataset. This setting is useful if the adapter returns more information than you want in the dataset.
Error	**Error**	A run-time error is raised if the adapter cannot map a source column to a dataset column because the mapping is missing or because the dataset schema does not contain the column. This setting is useful when you are working with a stringently defined schema and want to be sure that any deviations from the schema are flagged.

Previewing Data-Adapter Results

After configuring a data adapter, you can test how the adapter will fill a dataset.

To preview data-adapter results

1. Create a data adapter. For details, see Creating Data Adapters.
2. In the form or component designer, select the data adapter and then open the Properties window.
3. At the bottom of the window, click **Preview**.

   The **Data Preview** window opens.

4. Select a data adapter from the **Data Adapter** list, or choose **All DataAdapters** to see the effect of completely populating the dataset.
5. If the command referenced by the adapter's **SelectCommand** property requires parameters, fill in test parameter values in the **Parameters** grid.
6. Click **Fill Dataset** to perform the command.

   The results of the **SelectCommand** statement or stored procedure are displayed under Data. If the adapter gets data from more than one table in the data source (as might happen if it references a stored procedure that returns multiple results sets), the list of tables cataloged under Data tables appears twice. You can choose the table to preview by selecting it in the list.

7. Repeat for other adapters or with other parameter values. By default, each result set generated by the preview is appended onto others already in the dataset preview. To start with an empty dataset, click **Clear Table**.

ADO.NET Datasets

Datasets are containers — caches — in which you can store data to use in your application. Datasets are a fundamental part of the ADO.NET architecture, providing both high-performance data access as well as scalability.

The following topics provide information about ADO.NET **DataSet** objects and how to work with them in Visual Studio.

In This Section

Introduction to Datasets
Provides an overview of what ADO.NET datasets are, how they can by typed or untyped, what they are used for, and how they are structured.
Visual Studio Tools for Creating Datasets
Describes what features Visual Studios provides to allow you to create datasets and when you would choose which tool.
Creating Typed Datasets with the Component Designer
Describes how to create datasets when working in a form or component.
Creating Dataset Columns Using Expressions
Describes how to define columns in a dataset table that are based on calculations or other expressions rather than based directly on data in a data source.
Adding Tables to an Existing Dataset
Describes how to create new data tables in a typed dataset created earlier.
Adding Existing Typed Datasets to a Form or Component
Describes how to create an instance of a dataset on a form or component.
Adding Untyped Datasets to a Form or Component
Describes how to create a dataset that has no associated schema.
Handling Null Values in a Dataset
Explains how to control the representation of columns that contain null values.
Walkthrough: Mapping Data Source Tables to Dataset Tables
Describes how to load data from a database into a dataset based on a different schema using data adapter table and column mappings.

Manipulating Data Example Topics
Presents a series of specific example code topics for common tasks in working with data within your application using Visual Basic .NET.

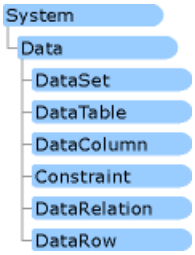
Introduction to Datasets

Datasets store data in a disconnected cache. The structure of a dataset is similar to that of a relational database; it exposes a hierarchical object model of tables, rows, and columns. In addition, it contains constraints and relationships defined for the dataset.

> **Note** You use datasets if you want to work with a set of tables and rows while disconnected from the data source. Using a dataset is not always an optimal solution for designing data access. For more information, see Recommendations for Data Access Strategies.

You can create and manipulate datasets using the following portions of the .NET Framework namespaces.

Dataset Namespace



The fundamental parts of a dataset are exposed to you through standard programming constructs such as properties and collections. For example:

- The DataSet class includes the Tables collection of data tables and the Relations collection of DataRelation objects.
- The DataTable class includes the Rows collection of table rows, the Columns collection of data columns, and the ChildRelations and ParentRelations collections of data relations.
- The DataRow class includes the RowState property, whose values indicate whether and how the row has been changed since the data table was first loaded from the database. Possible values for the RowState property include **Deleted**, **Modified**, **New**, and **Unchanged**.

Datasets, Schemas, and XML

An ADO.NET dataset is one view — a relational view — of data that can be represented in XML. In Visual Studio and the .NET Framework, XML is the format for storing and transmitting data of all kinds. As such, datasets have a close affinity with XML. This relationship between datasets and XML enables you to take advantage of the following features of datasets:

- The structure of a dataset — its tables, columns, relationships, and constraints — can be defined in an XML Schema. XML Schemas are a standards-based format of the W3C (World Wide Web Consortium) for defining the structure of XML data. Datasets can read and write schemas that store structured information using the ReadXmlSchema and WriteXmlSchema methods. If no schema is available, the dataset can infer one (via its InferXmlSchema method) from data in an XML document that is structured in a relational way. For more information about datasets and schemas, see Introduction to XML Schemas.
- You can generate a dataset class that incorporates schema information to define its data structures (such as tables and columns) as class members. (See "Typed versus Untyped Datasets" below).
- You can read an XML document or stream into a dataset using the dataset's ReadXML method and write a dataset out as XML using the dataset's WriteXML method. Because XML is a standard interchange format for data between different applications, this means that you can load a dataset with XML-formatted information sent by other applications. Similarly, a dataset can write out its data as an XML stream or document, to be shared with other applications or simply stored in a standard format.
- You can create an XML view (an XMLDataDocument object) of the contents of a dataset, and then view and manipulate the data using either relational methods (via the dataset) or XML methods. The two views are automatically synchronized as they are changed.

Typed versus Untyped Datasets

Datasets can be typed or untyped. A typed dataset is a dataset that is first derived from the base **DataSet** class and then uses information in an XML Schema file (an .xsd file) to generate a new class. Information from the schema (tables, columns, and so on) is generated and compiled into this new dataset class as a set of first-class objects and properties.

> **Note** For more information about dataset schemas, see XML Schemas and Data.

Because a typed **DataSet** class inherits from the base **DataSet** class, the typed class assumes all of the functionality of the **DataSet** class and can be used with methods that take an instance of a **DataSet** class as a parameter

An untyped dataset, in contrast, has no corresponding built-in schema. As in a typed dataset, an untyped dataset contains tables, columns, and so on — but those are exposed only as collections. (However, after manually creating the tables and other data elements in an untyped dataset, you can export the dataset's structure as a schema using the dataset's WriteXmlSchema method.)

You can use either type of dataset in your applications. However, Visual Studio has more tool support for typed datasets, and they make programming with the dataset easier and less error-prone.

Contrasting Data Access in Typed and Untyped Datasets

The class for a typed dataset has an object model in which its tables and columns become first-class objects in the object model. For example, if you are working with a typed dataset, you can reference a column using code such as the following:

```
' Visual Basic
' This accesses the CustomerID column in the first row of
' the Customers table.
Dim s As String
s = dsCustomersOrders1.Customers(0).CustomerID

// C#
// This accesses the CustomerID column in the first row of
// the Customers table.
string s;
s = dsCustomersOrders1.Customers[0].CustomerID;
```

In contrast, if you are working with an untyped dataset, the equivalent code is:

```
' Visual Basic
Dim s As String
s = CType(dsCustomersOrders1.Tables("Customers").Rows(0).Item("CustomerID"), String)

// C#
string s = (string) dsCustomersOrders1.Tables["Customers"].Rows[0]["CustomerID"];
```

Typed access is not only easier to read, but is fully supported by IntelliSense in the Visual Studio Code Editor. In addition to being easier to work with, the syntax for the typed dataset provides type checking at compile time, greatly reducing the possibility of errors in assigning values to dataset members. Access to tables and columns in a typed dataset is also slightly faster at run time because access is determined at compile time, not through collections at run time.

Even though typed datasets have many advantages, there are a variety of circumstances under which an untyped dataset is useful. The most obvious scenario is that no schema is available for the dataset. This might occur, for example, if your application is interacting with a component that returns a dataset, but you do not know in advance what its structure is. Similarly, there are times when you are working with data that does not have a static, predictable structure; in that case, it is impractical to use a typed dataset, because you would have to regenerate the typed dataset class with each change in the data structure.

More generally, there are many times when you might create a dataset dynamically without having a schema available. In that case, the dataset is simply a convenient structure in which you can keep information, as long as the data can be represented in a relational way. At the same time, you can take advantage of the dataset's capabilities, such as the ability to serialize the information to pass to another process, or to write out an XML file.

Dataset Case Sensitivity

Within a dataset, table and column names are by default case-insensitive — that is, a table in a dataset called "Customers" can also be referred to as "customers." This matches the naming conventions in many databases, including SQL Server, where the names of data elements cannot be distinguished only by case.

> **Note** Unlike datasets, XML documents are case-sensitive, so the names of data elements defined in schemas are case-sensitive. For example, schema protocol allows the schema to contain define a table called "Customers" and a different table called "customers." This can result in name collisions when a schema is used to generate a dataset class. For more information, see XML Elements, Attributes, and Types.

However, case sensitivity can be a factor in how data is interpreted within the dataset. For example, if you filter data in a dataset table, the search criteria might return different results depending on whether the comparison is case-sensitive or not. You can

control the case sensitivity of filtering, searching, and sorting by setting the dataset's CaseSensitive property. All the tables in the dataset inherit the value of this property by default. (You can override this property for each individual table.)

Populating Datasets

A dataset is a container; therefore, you need to fill it with data. When you populate a dataset, various events are raised, constraint checking applies, and so on. For more information about updating a dataset and the issues surrounding updates, see Dataset Updates in Visual Studio .NET.

You can populate a dataset in a variety of ways:

- Call the **Fill** method of a data adapter. This causes the adapter to execute an SQL statement or stored procedure and fill the results into a table in the dataset. If the dataset contains multiple tables, you probably have separate data adapters for each table, and must therefore call each adapter's **Fill** method separately.

  For more information about how datasets are filled, see Introduction to Data Adapters and Creating Data Adapters. For more information on how to use a data adapter to populate a dataset, see Populating a DataSet from a DataAdapter.

- Manually populate tables in the dataset by creating **DataRow** objects and adding them to the table's **Rows** collection. (You can only do this at run time; you cannot set the **Rows** collection at design time.) For more information, see Adding Data to a Table.
- Read an XML document or stream into the dataset. For more information, see the ReadXml method.
- Merge (copy) the contents of another dataset. This scenario can be useful if your application gets datasets from different sources (different XML Web services, for example), but needs to consolidate them into a single dataset. For more information, see the DataSet.Merge method.

Record Position and Navigation in Datasets

Because a dataset is a fully disconnected container for data, datasets (unlike ADO recordsets) do not need or support the concept of a current record. Instead, all records in the dataset are available.

Because there is no current record, there is no specific property that points to a current record and there are no methods or properties for moving from one record to another. (In contrast, ADO recordsets support an absolute record position and methods to move from one record to the next.) You can access individual tables in the dataset as objects; each table exposes a collection of rows. You can treat this like any collection, accessing rows via the collection's index or using collection-specific statements in your programming language.

> **Note** If you are binding controls in a Windows Forms to a dataset, you can use the form's binding architecture to simplify access to individual records. For more information, see Navigating Data in Windows Forms.

Related Tables and DataRelation Objects

If you have multiple tables in a dataset, the information in the tables might be related. A dataset has no inherent knowledge of such relationships; to work with data in related tables, therefore, you can create DataRelation objects that describe the relations between the tables in the dataset. **DataRelation** objects can be used to programmatically fetch related child records for a parent record, and a parent record from a child record.

For example, imagine customer and order data such as that in the Northwind database. The Customers table might contain records such as the following:

```
CustomerID   CompanyName               City
ALFKI        Alfreds Futterkiste       Berlin
ANTON        Antonio Moreno Taquerias  Mexico D.F.
AROUT        Around the Horn           London
```

The dataset might also contain another table with order information. The Orders table contains a customer ID as a foreign key column. Selecting only some of the columns in the Orders table, it might look like the following:

```
OrderId    CustomerID    OrderDate
10692      ALFKI         10/03/1997
10702      ALFKI         10/13/1997
10365      ANTON         11/27/1996
10507      ANTON         4/15/1997
```

Because each customer can have more than one order, there is a one-to-many relationship between customers and orders. For example, in the table above, the customer ALFKI has two orders.

You can use a **DataRelation** object to get related records from a child or parent table. For example, when working with the record describing the customer ANTON, you can get the collection of records describing the orders for that customer. Similarly, if you are working with the record describing order number 10507, you can use a **DataRelation** object to get the record describing the customer for that order (ANTON).

Constraints

As in most databases, datasets support constraints as a way to ensure the integrity of data. Constraints are rules that are applied when rows are inserted, updated, or deleted in a table. You can define two types of constraints:

- A unique constraint that checks that the new values in a column are unique in the table.
- A foreign-key constraint that defines rules for how related child records should be updated when a record in a master table is updated or deleted.

In a dataset, constraints are associated with individual tables (foreign-key constraints) or columns (a unique constraint, one that guarantees that column values are unique). Constraints are implemented as objects of type **UniqueConstraint** or **ForeignKeyConstraint**. They are then added to a table's Constraints collection. A unique constraint can alternatively be specified by simply setting a data column's Unique property to **true**.

The dataset itself supports a Boolean EnforceConstraints property that specifies whether constraints will be enforced or not. By default, this property is set to **true**. However, there are times when it is useful to temporarily turn constraints off. Most often, this is when you are changing a record in such a way that it will temporarily cause an invalid state. After completing the change (and thereby returning to a valid state), you can re-enable constraints.

In Visual Studio, you create constraints implicitly when you define a dataset. By adding a primary key to a dataset, you implicitly create a unique constraint for the primary-key column. You can specify a unique constraint for other columns by setting their Unique property to **true**.

You create foreign-key constraints by creating a **DataRelation** object in a dataset. In addition to allowing you to programmatically get information about related records, a **DataRelation** object allows you to define foreign-key constraint rules.

For more information about using **DataRelation** objects as foreign-key constraints, see Introduction to DataRelation Objects. For more information about creating constraints programmatically, see Adding Constraints to a Table.

Updating Datasets and Data Stores

When changes are made to records in the dataset, the changes have to be written back to the database. To write changes from the dataset to the database, you call the **Update** method of the data adapter that communicates between the dataset and its corresponding data source.

The **DataRow** class used to manipulate individual records includes the **RowState** property, whose values indicate whether and how the row has been changed since the data table was first loaded from the database. Possible values include **Deleted**, **Modified**, **New**, and **Unchanged**. The **Update** method examines the value of the **RowState** property to determine which records need to be written to the database and what specific database command (add, edit, delete) should be invoked.

For more information about updating data, see Dataset Updates in Visual Studio .NET.

Visual Studio Tools for Creating Datasets

Visual Studio provides the following ways to create datasets:

- The Component Designer, which allows you to drag data elements onto a form or component from the Toolbox or Server Explorer. Visual Studio can create the objects you need for your dataset, including a schema based on the structure of the original data source. When you are creating a form, the Component Designer appears as a tray at the bottom of the design surface. This method allows you to create either typed or untyped datasets.
- The XML Designer, which allows you to create a schema and generate a typed dataset based on it.

You can also create datasets dynamically in code; in that case, the dataset is untyped. (If you have created a typed dataset by generating it from a schema, you can change its structure dynamically in code as well.)

> **Note** When you deploy an application that includes Visual Studio data-access components, you must make sure that the user installing the application has version 2.7 or later of the Microsoft Data Access Components (MDAC). For more information, see Adding a Launch Condition for Microsoft Data Access Components.

Steps in Generating a Typed Dataset

When you generate a typed dataset, you actually perform a series of discrete steps:

1. Obtain an XML Schema (.xsd file). You might add a schema to your project in these ways:

   - Create a schema based on the data structure you are working with. If you use the Component Designer to add a data adapter to your form or component, the adapter can read the data-source structure and translate it into an .xsd file.
   - Create a schema manually using the XML Designer.
   - Create a reference to an XML Web service or other component that returns a dataset. As part of the reference, Visual Studio creates a local copy of the schema.

     For more information about dataset schemas, see XML Schemas and Data.

2. Generate a dataset class. In this step, Visual Studio derives a class from the base **DataSet** class in the **System.Data** namespace. It then uses the information in the schema to create strongly typed members representing the data tables and data columns for the dataset.

   Under most circumstances, Visual Studio generates this dataset class automatically when the schema is added to the project.

3. Create an instance of the derived dataset class from Step 2 to use on a form or component.

When you work with a dataset in your application, you are actually working with an instance of the dataset class (like that one created in Step 3).

Using the Component Designer

In general, you use the Component Designer when you want Visual Studio to generate a schema and a typed dataset class for you. In the Component Designer, you add one or more data adapters to your form or component. The adapters push data shape information into the dataset (via their FillSchema methods). The dataset can then write the resulting structure out as an XML Schema (.xsd file) in the project. At that point, you can have Visual Studio generate an instance of the typed dataset class to be added to your form or component.

The Component Designer is therefore an indirect way to create a dataset — you do not explicitly define the tables and columns in the dataset. Instead, you implicitly define them by configuring the data adapter. You can do this by establishing the SQL queries or stored procedures that the adapter uses to exchange data with the data source. You can also use the adapter's TableMappings property to specify which columns are included in the dataset and what their names are.

After configuring the data adapter, you generate the dataset from it. If you change the data adapter after generating the dataset — for example, by changing table mappings — you must then regenerate the dataset to reflect these changes.

The disadvantages of using the Component Designer are:

- You initially have no direct control over the schema; you can control the dataset definition only by configuring the data adapter from which Visual Studio generates the schema. After generating the schema, however, you can edit it using the XML Designer.

- You must manually regenerate the schema (and corresponding dataset class file) after changing a data adapter. For example, if you change the SQL statement used to fill a dataset, you must change the dataset schema as well.
- There are some dataset functions you cannot perform using the Component Designer alone, such as defining **DataRelation** objects. In that case, you must use the XML Designer.

Using the XML Designer

You use the XML Designer when you want to control more precisely how the schema is defined or if you cannot generate the schema from a data source. You can use the XML Designer to create a schema in two ways:

- Drag database elements (for example, column names) from Server Explorer onto the designer. This creates the schema that is initially generated from the database structure and which you can then modify as needed.
- Create a schema file yourself. This is useful when you are designing a schema without reference to any external data source.

In both cases, you can then generate an instance of a typed **DataSet** class based on the schema that you create and use it on a form or component.

The XML Designer allows you to add, remove, or modify elements. The XML Designer also allows you to perform functions (such as adding **DataRelation** objects) that cannot be accomplished using the Component Designer.

When you use the XML Designer, you are editing an .xsd file. Very frequently, your project will also contain a typed dataset class file based on the .xsd file. If you save the changes in the .xsd file, the corresponding class file is regenerated to reflect the updated schema. Visual Studio can keep the .xsd and corresponding class file synchronized by continuously regenerating the class file as you make changes in the .xsd file. You can turn off this functionality, which you might do if you are editing a schema file for which you do not need a class file.

The disadvantages of working in the XML Designer are:

- The XML Designer offers a slightly lower level of integration with other data tools in Visual Studio.
- The .xsd file is not validated against any external data source. For example, if you use the XML Designer to modify a dataset schema, you must also modify any data adapters that interact with the dataset.
- Some familiarity with XML Schemas and XML is assumed.

Creating Typed Datasets with the Component Designer

When you are using a dataset with a form or component, you can use the Component Designer to define the dataset schema and class file. You can then add an instance of the dataset to the form or component you are working with.

When you are editing a form, the Component Designer appears as a tray at the bottom of the designer window. The tray opens automatically as soon as you add a component or nonvisual control to the form. Instances of dataset classes are displayed there, where you can select them in order to set properties or write event handlers for them.

To create a dataset in the Component Designer

1. Add one or more data adapters to the form or component that specify what data you want to put in the dataset. For more information, see Creating Data Adapters.
2. In the Component Designer, select the adapter or adapters that will be used to transfer data between the data source and the dataset.

   Typically, each data adapter accesses data in a single table. Therefore, to create a dataset containing multiple data tables, you should select all the adapters for the tables you want to work with.

   > **Note** Adding multiple tables to the dataset does not automatically create a relationship between the tables; you must do that manually after creating the dataset. For more information, see Creating DataRelation Objects with the XML Designer.

3. From the **Data** menu, choose **Generate Dataset**.

   The **Generate DataSet** dialog box appears.

4. Select **New** and then specify a name for the new dataset. If you want to add the dataset to your form or component, click **Add an instance of this DataSet to the designer**.

   Visual Studio uses the information in the data adapters to generate an XML Schema file (.xsd), which is added to the project using the name you specified. Visual Studio then generates a new dataset class file based on the schema.

   > **Note** The new dataset class file is visible in **Solution Explorer** only if you select **Show All Files**.

   If you indicated that you wanted an instance of the dataset, the instance is added to the form or component using the name you specified with a numeric suffix. For example, if you named the dataset **dsAuthors**, the instance is named **dsAuthors1**.

   > **Note** If you accept the default dataset name of DataSet1, the instance in your form or component will be named DataSet11 because of the numeric suffix that is automatically added.

5. If you added a dataset to the form or component, add code to populate it. Most frequently, you do this by calling the **Fill** method of the data adapters. For more information, see Populating a DataSet from a DataAdapter.
6. If you want to update the dataset and database, add code to the form or component to do so. For more information about updating, see Dataset Updates in Visual Studio .NET.

Creating Dataset Columns Using Expressions

As in some databases, a data table in a dataset can contain columns in which the value is calculated rather than read from a store. For example, in an orders detail record, it might make sense to define an ExtendedPrice column by multiplying the quantity and the price, rather than actually storing the total in the record. Calculated columns can also add or count values in child records and filter other records. You can define calculated columns using expressions.

The syntax of the expression consists of standard arithmetic, Boolean, and string operators and literal values. You can reference a data value using its column name (as you would in an SQL statement) and include aggregate functions such as Count.

For example, the expression for an ExtendedPrice column based on the UnitPrice and Quantity columns of the current record might simply be:

```
UnitPrice * Quantity
```

To refer to columns in child tables, you can use the reserved word "Child." followed by the name of the column. For example, the following expression returns the average value of the Price column in all related child records:

```
Avg(Child.Price)
```

Column Expressions in Typed Datasets

You can create the column and expression for typed datasets in the XML Designer. For more information about creating columns using the XML Designer, see Creating Tables in XML Schemas.

To create column expressions in typed datasets

1. If the schema is not already open in the XML Designer, double-click the XML Schema (.xsd) file in Solution Explorer.
2. In the grid representing the table you want to work with, add a new column by performing the following steps:
   a. In the first blank line of the table grid, select **Element** from the drop-down list.
   b. In the next box in the same line, enter a name for the column, using a valid column identifier.
   c. In the next box, select an appropriate data type for the results of the calculation.
3. Select the new column in the table grid, and then in the Properties window, enter an expression in the **Expression** property. For more information about column expression syntax, see the DataColumn.Expression property.

Column Expressions in Untyped Datasets

If you are working with an untyped dataset, you cannot use the XML Designer because there is no schema (unless you generate one from the dataset using WriteXmlSchema). However, you can create the column and expression in the form or Component Designer.

To create column expressions in untyped datasets

1. Select the untyped dataset in the form or component and open the Properties window.
2. Click the button in the **Tables** property to open the **DataTable Collection Editor** dialog box.
3. In the collection editor, click the button in the **Columns** property to open the **DataColumn Collection Editor** dialog box.
4. Click **Add** to create a new column.
5. Select the new column, and in the **Properties** grid, set the **ColumnName** property to provide a name by which you can refer to the column in code.

   Note You can also set the (Name) property to give the column a different name at design time.

6. Select an appropriate data type for the results of the calculation.
7. Enter an expression in the **Expression** property. For more information about column-expression syntax, see the DataColumn.Expression property.

Code: Creating an Expression Column (Visual Basic):

Adding Tables to an Existing Dataset

Occasionally you might need to add a data table to a dataset that has already been generated. One way is to delete the dataset and regenerate it manually to include the new table. However, in that case you might lose additional dataset information (including constraints and **DataRelation** objects) that were added to the dataset after it was generated.

You can add tables to an existing dataset two ways:

- Use the Component Designer in a form or component. This is an easy solution that allows you to drag elements onto the form or component and then regenerate a modified dataset.
- Use the XML Designer to modify the dataset schema. This strategy is useful if you are comfortable using the XML Designer and do not want or need to open a form or component. Adding a table using the XML Designer is similar to creating the schema manually. For more information, see Creating Tables in XML Schemas.

To add a table to an existing dataset using the Component Designer

1. In the form or component you are working with, add a data adapter that references the table you want to add.
2. Select the data adapter, and then from the **Data** menu, choose **Generate Dataset**.

   The **Generate Dataset** dialog box is displayed.
3. Under **Choose a Dataset**, choose **Existing**, and then select the name of the dataset to add the table to.
4. Under **Choose which table(s) to add to the dataset**, select the names of all the tables that you want to add to the dataset. The list includes tables from all available data adapters.
5. If you want to create an instance of the modified dataset on your form or component, select **Add an instance of this dataset to the designer**.
6. Click **OK** to generate an updated dataset.

   Information about the added table is added to the dataset schema and to the derived dataset class file. Existing information (including tables, constraints, and relationships) is left intact.

Adding Existing Typed Datasets to a Form or Component

You will frequently need to add a typed dataset to a form or component so that you can manipulate data, bind controls to the dataset, and so on. When you add a dataset, you are actually creating an instance of the typed dataset class on your form or component. The typed dataset class must already exist and can come from several sources:

- You created it by generating it in another form or component in your project. For more information, see Creating Typed Datasets with the Component Designer.
- You created it manually in the XML Designer. For more information, see Creating XML Schemas and Datasets.
- You created a reference to an XML Web service or other component that returns a dataset. For more information, see Accessing an XML Web Service in Managed Code.

You can add an untyped dataset to a form or component as well, but you create it in the form or component rather than adding an instance of a typed dataset class. For more information, see Adding Untyped Datasets to a Form or Component.

To add an existing dataset to a form or component

1. Open the form or component you want to work with. If necessary, switch to **Design** view of the designer.
2. From the **Data** tab of the Toolbox, drag a **DataSet** object onto the designer.

   The **Choose a Dataset** dialog box appears.

3. Select **Typed Dataset**, and then from the drop-down list, select the dataset you want to use, and then click **OK**.

   The drop-down list is populated with a list of all typed dataset classes in your project.

   > **Tip** If you have added an XML Web service or component but cannot see the dataset's schema in Solution Explorer, open up the node for the reference. If you still do not see the schema, double-check that the XML Web service or component is returning a typed dataset.

   An instance of the typed dataset class is added to the form or component.

4. Add code to the form or component to fill the dataset.

   If the dataset represents data from a database, you generally call the **Fill** method of a data adapter to execute an SQL statement or stored procedure that fetches the data for the dataset. For more information, see Populating a DataSet from a DataAdapter. The following example shows how you might fill the table Customers in the dataset dsCustomersOrders (whose instance is called dsCustomersOrders1):

   ```
   ' Visual Basic
   oleDbDataAdapter1.Fill( dsCustomersOrders1, "Customers" )

   // C#
   oleDbDataAdapter1.Fill( dsCustomersOrders1, "Customers");
   ```

   If the dataset represents information returned by an XML Web service or a component, you need to load the dataset by invoking the method that returns data. You then typically need to merge the data returned by the XML Web service or component into the dataset on your form. The following example shows how to create an instance of an XML Web service, invoke its method called GetCustomersDataset, and load it into a local dataset called dsCustomers1:

   ```
   ' Visual Basic
   Dim ws1 As New MyServer.CService1()
   dsCustomers1.Merge(ws1.GetCustomersDataset())

   // C#
   MyServer.CService1 ws1 = new MyServer.CService1();
   dsCustomers1.Merge(ws1.GetCustomersDataset());
   ```

   You can also fill the dataset by creating data programmatically. For more information, see Adding Data to a Table.

5. If your application requires that you write information from the dataset to a database, add code to the form or component

to do this.

If the dataset is filled using a data adapter, you can call the data adapter's **Update** method to write changed data back the database. For more information, see Updating the Database with a DataAdapter and the DataSet.

Adding Untyped Datasets to a Form or Component | Populating a DataSet from a DataAdapter | Data Walkthroughs

Adding Untyped Datasets to a Form or Component

An untyped dataset is an instance of the DataSet class that you create in a form or component. Unlike a typed dataset, an untyped dataset is not an instance of a class generated using an XML Schema (.xsd) file. As a consequence, an untyped dataset has no inherent structure. You create the tables, columns, constraints, and **DataRelation** objects yourself at design time in the Properties window, at run time in code, or by allowing a data adapter's mappings to do so when you use the data adapter to fill the dataset.

> **Note** Although an untyped dataset is not based on a class that incorporates a schema, after building the untyped dataset, you can export its structure to a schema file. For more information, see the DataSet.WriteXmlSchema method.

Creating the Dataset

The instructions below describe how to create an untyped dataset using the Component Designer while editing a form or component. For more information about how to create an untyped dataset at run time in code, see Creating a DataSet and Adding a DataTable to a DataSet.

> **Note** When you deploy an application that includes Visual Studio data-access components, you must make sure that the user installing the application has version 2.7 or later of the Microsoft Data Access Components (MDAC). For more information, see Adding a Launch Condition for Microsoft Data Access Components.

To create an untyped dataset at design time

1. From the **Data** tab of the Toolbox, drag a **DataSet** element onto the form or component you are working with.

   The **Choose a Dataset** dialog box is displayed.

2. Select **Untyped Dataset** and click **OK**.

   A blank dataset is added to the form or component.

3. If you want to give the dataset a new name, select it, open the Properties window, and edit the following two properties.

   - **(Name)** This property sets the object name by which you refer to the dataset in code.
   - **DataSetName** If you export the dataset to an XML document, this property sets the name of the dataset in the document (that is, the name of the topmost element). Setting this property can help avoid problems with name duplication or case sensitivity.

Adding Tables and Columns

You can use the Properties window to create the structure of the untyped dataset. The dataset includes a Tables property that is a collection of the DataTable objects defined for the dataset. Each table in turn supports a Columns property that is a collection of DataColumn objects. To create tables and columns, therefore, you use the Collection Editor feature of the Properties window.

> **Note** You cannot create records in an untyped dataset at design time; you can populate a dataset only at run time. The **Rows** collection of a dataset is therefore not available in the Properties window.

To add tables and columns to the dataset

1. In the form or component, select the dataset and open the Properties window.
2. In the **Tables** property, click the button to open the **DataTable Collection Editor** dialog box.
3. Click **Add** to create a new table. If you want to rename the table, select it and in the right pane of the properties grid, change the value of the **(Name)** property.

   > **Note** The names of all tables in all datasets in the form or component share the same namespace. Therefore, you cannot use a table name in one dataset if that name is in use in another dataset.

4. To add columns to the table, do the following:
   a. Make sure the table you are working with is selected in the **Members** list, and then in the **Properties** grid on the right, click the button in the **Columns** property to display the **DataColumn Collection Editor** dialog box.
   b. Click **Add** to create a new column, and then set the new column's properties in the grid on the right. Some of the properties allow you to set column constraints, such as a unique constraint or a non-null constraint. Typical properties to set are listed in the following table.

Property	Description

AllowDBNull	A Boolean value indicating whether the column can be left blank in a given record.
ColumnName	The name of the column in the table's **Tables** collection, which is how the column can be referenced in code.
DataType	A .NET Framework data type to be enforced for the column. If you import or export an XML document to or from this dataset, data types are automatically converted to schema types (for example, `System.String` is converted to `xs:string` and vice versa). Select a data type from the drop-down list.
ReadOnly	A Boolean value indicating whether a column can be changed.
Unique	A Boolean value indicating a unique constraint on the column. You always set this to **true** for a primary key column, but it can be set for any column.
(Name)	An instance name for the column used only at design time.

   c. Repeat Step b for each column you want to add.
   d. When you are finished adding columns for the current table, click **OK** to close the **DataColumn Collection Editor** dialog box.
5. To set a primary key for the table, use the drop-down list in the **PrimaryKey** property.
   a. In the drop-down list, select the check box next to each part of the primary key.
   b. After selecting one or more columns for the primary key, you can expand the **PrimaryKey** property and set properties for each primary key column. The **Unique** property is automatically set for all the columns that are part of the primary key.
6. Repeat Steps 3 through 5 for each table and set of columns that you want to add to the dataset.

Adding Constraints

You can define two types of constraints in a dataset:

- A unique constraint that checks that the new values in a column are unique in the table.
- A foreign-key constraint that defines rules for how related child records should be updated when a record in a master table is updated or deleted.

To add constraints to an untyped dataset at design time

1. In the form or component, select the dataset and open the Properties window.
2. Click the button in the **Tables** property to open the **Tables Collection Editor**.
3. Select the table to add a constraint to, and then click the button in the **Constraints** property to open the **Constraints Collection Editor**.
4. Click **Add** and then select **Unique Constraint** or **Foreign Key Constraint** from the drop-down list.

   The **Unique Constraint** or **Foreign Key Constraint** dialog box id displayed. For help on filling in these dialog boxes, press F1.

Adding Relations

You can also create relationships (**DataRelation** objects) between tables in the dataset at design time. For more information about **DataRelation** objects, see Introduction to DataRelation Objects.

To add a DataRelation object to an untyped dataset at design time

1. In the form or component, select the dataset and open the Properties window.
2. In the **Relations** property, click the button to open the **DataRelation Collection Editor** dialog box.
3. Click **Add** to create a new data relation.

   The **Data Relation Editor** dialog box opens with default values for the new relationship.

4. In the dialog box, set values according to the following table.

Value	Description
Name	The name by which you can refer to this **DataRelation** object in code. A typical name includes the names of both tables being related (for example, `CustomersOrders`).

Parent table	The table containing the parent records. Select a table from the drop-down list.
Child table	The table containing child records. Select a table from the drop-down list.
Parent column	The names of the columns that make up the primary keys in the parent table. You can select column names from the drop-down list or type in a column name (for example, if you know the name of a column that will be defined at run time).
Child column	The names of the columns that make up the foreign keys in the child table.
Enforce constraints	A Boolean value indicating whether the **DataRelation** object will be used to cascade changes from the parent table to the child table and vice versa. **Note** If you choose to enforce constraints, a foreign key constraint is added to the parent table.
Update rule Delete rule Accept/reject rule	The nature of the cascaded change that should be made in the child table when changes occur in the parent table. For more information about the settings for these values, see Introduction to DataRelation Objects.

5. Click **OK** to save the changes to this relationship.
6. Repeat Steps 3 through 5 for each relationship you want to create.

Introduction to DataRelation Objects | Adding Constraints to a Table | DataSet.WriteXmlSchema Method

Handling Null Values in a Strongly Typed Dataset

In a typed dataset, you can control the representation of columns that contain **null** values. This behavior is only available when retrieving column values through their typed accessors. If you retrieve the value by means of the table's row index or column index, you will not be able to set the return value.

To set the value to return when a DataColumn's value is null

1. Open the dataset in the XML Designer.
2. Select an Element whose type is NOT an unnamed (or anonymous) type.
3. In the Properties window, select the **NullValue** property.
4. Do one of the following:

   - From the drop-down list select the appropriate value:

Value	Description
(Empty)	To have null values return as String.Empty **.**
(Null)	To have null values return as **null.**
(Throw)	To have null values throw an Exception.

   - - or -
   - Set the property to any custom value.

Walkthrough: Mapping Data Source Tables to Dataset Tables

The structure of tables in a dataset does not always match the structure of tables in a data source. There might be several reasons for this:

- The dataset was created from an existing schema that uses different names than those in the data source.
- You want to change data element names in the dataset for convenience, readability, translation to or from a foreign language, or other reason.
- You want to control the names of typed data members when you generate a dataset from the adapter.

To enable you to match up tables and columns in the data source with those in the dataset, you can set the **TableMappings** property of a data adapter. This property contains information that establishes a correspondence between data source table columns and dataset table columns. When the adapter reads data from the data source, **TableMappings** property is used to determine where in the dataset to write the data.

This walkthrough gives you brief overview of how to set up table mappings in a data adapter. The scenario for the walkthrough assumes that you are working with a schema provided to you by someone else. You will map the columns from a table in your database (in this case, the Customers table of the Northwind database) to the columns defined in the schema.

In order to complete this walkthrough, you will need:

- Access to a server with the Northwind SQL Server sample database.

The walkthrough is split into a number of smaller pieces:

- Creating a Windows Form. The form is used only to illustrate how to create the mapping; you could use any form or component.
- Creating a dataset with a pre-defined schema. The walkthrough contains a simple but complete schema that you can copy and paste into Visual Studio to simulate a schema you might have gotten from someone else.
- Creating and configuring the data adapter in which you will map the data source to the dataset.
- Adding the **DataGrid** control to show the effect of the mapping.

Creating the Project and Form

This walkthrough uses a Windows Form as the container on which you will create the data adapter and dataset. It is not necessary that you use a Windows Form — you could also use a Web Forms page or a component — but a Windows Form is easy to work with and allows you later to use a **DataGrid** control to see the effect of the mappings.

To create the project and form

1. From the **File** menu, point to **New**, and then choose **Project**.
2. In the **Project Types** pane, choose **Visual Basic Projects** or **Visual C# Projects**, and then in the **Templates** pane, choose **Windows Application**.
3. Assign a name to the project that will be unique and will conform to the naming conventions you use. For example, you might name this project **Walkthrough_Mappings**. After you have assigned a name, click **OK**.

   Visual Studio creates a new project and displays a new form in the Windows Form Designer.

Creating the Schema and Dataset

For the walkthrough, imagine that someone has provided you with a schema that defines a Customers table. The schema defines a Customers table that is slightly different from the one in your Northwind database.

In this section, you will add a schema in your project. The actual schema layout (the XML that defines the schema) is provided below. By default, the XML Designer generates a class file based on the schema and derived from the DataSet class. The resulting class file defines the typed dataset class that you use in your application.

For more information about dataset and how they are defined, see Introduction to Datasets.

To add the schema

1. In Solution Explorer, right-click the name of your project, choose **Add**, and then choose **Add New Item**.
2. In the **Templates** pane, choose **DataSet**, name the new item **dsCustomers**, and then click **Open**.

   The XML Designer opens with a new, blank dataset schema.

3. Click the **XML** tab at the bottom.
4. Copy the following schema text and then paste it into the XML view of the designer, completely overwriting the schema already in the file.

   Tip If the < and > symbols are replaced with
   <
   and
   >
   when you paste, remove the pasted text, and then re-paste the schema by right clicking the design surface and selecting **Paste as HTML** from the shortcut menu.

```
<?xml version="1.0" encoding="utf-8" ?>
<xs:schema id="dsCustomers" targetNamespace="http://www.tempuri.org/dsCustomers.xsd" xmln
s="http://www.tempuri.org/dsCustomers.xsd" xmlns:xs="http://www.w3.org/2001/XMLSchema" xm
lns:msdata="urn:schemas-microsoft-com:xml-msdata" elementFormDefault="qualified">
   <xs:element name="dsCustomers" msdata:IsDataSet="true">
      <xs:complexType>
         <xs:choice maxOccurs="unbounded">
            <xs:element name="Customers">
               <xs:complexType>
                  <xs:sequence>
                     <xs:element name="CustID" type="xs:string" />
                     <xs:element name="CompName" type="xs:string" />
                     <xs:element name="ContName" type="xs:string" minOccurs="0" />
                     <xs:element name="ContTitle" type="xs:string" minOccurs="0" />
                  </xs:sequence>
               </xs:complexType>
            </xs:element>
         </xs:choice>
      </xs:complexType>
         <xs:key name="Constraint1" msdata:PrimaryKey="true">
            <xs:selector xpath=".//Customers" />
            <xs:field xpath="CustID" />
         </xs:key>
      </xs:element>
   </xs:schema>
```

5. Save the schema and close it.
6. Check that you have a dataset class file based on the schema. In Solution Explorer, click the **Show All Files** button, and then expand the node for the new schema. You should see a class file (with extension of .vb or .cs) underneath the schema.

Now that you have a schema and related dataset class file, you can add an instance of the dataset to your form.

To add the dataset to the form

1. Click the **Form1** tab at the top to return to the Windows Form designer and your form.
2. From the **Data** tab of the Toolbox, drag the **DataSet** element onto the form.

   The **Add Dataset** dialog box is displayed.

3. Select **Typed Dataset** and then from the **Name** list, choose the dataset named **dsCustomers**. The dataset name is prefixed with your project name.

   An instance of the dataset is added to the form under the name dsCustomers1.

Creating a Data Adapter and Table Mapping

With the dataset defined, you can configure the other half of your data access story: the data adapter that will read data from the database and fill it into the dataset. The data adapter will contain the table mapping that matches the database columns to those in the dataset.

Adding the Data Adapter

The first step is to create the data adapter, which you can do using a wizard.

To add a data adapter

1. From the **Data** tab of the Toolbox, drag the **OleDbDataAdapter** element onto the form.

   The **Data Adapter Configuration Wizard** dialog box is launched.

2. In the wizard, do the following:
   a. In the second pane, create or choose a connection pointing to the SQL Server Northwind database.

      Security Note Storing connection-string details (such as the server name, user name, and password) can have implications for the security of your application. Using Windows Integrated Security is a more secure way to control access to a database. For more information, see Database Security.

   b. In the third pane, specify that you want to use an SQL statement to access the database.
   c. In the fourth pane, create the following SQL statement:

      ```
      SELECT CustomerID, CompanyName, ContactName, ContactTitle
      FROM Customers
      ```

      For assistance building the SQL statement, click **Query Builder** to launch the **Query Builder**.

      Note In this walkthrough, you will populate the dataset with all the rows from the Customers table. In production applications, you typically optimize data access by creating a query that returns only the columns and rows you need. For an example, see Walkthrough: Displaying Data in a Windows Form Using a Parameterized Query.

   When the wizard is complete, you will have a connection (**OleDbConnection1**) containing information about how to access your database. You will also have a data adapter (**OleDbDataAdapter1**) that contains a query defining what table and columns in the database you want to access.

Creating the Table Mapping

Now that you have a data adapter on the form, you can configure its table mappings.

To create the mappings

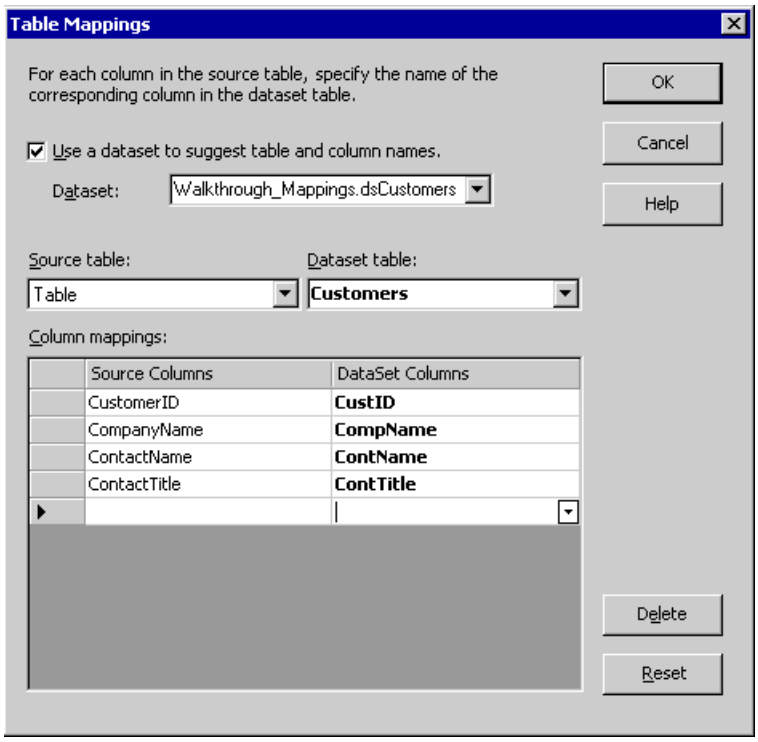
1. Select the data adapter at the bottom of the form.
2. In the Properties window, click the button in the **TableMappings** property.

   The Table Mapping dialog box is displayed.

3. Check **Use a dataset to suggest table and column names** and select **Walkthrough_Mappings.dsCustomers** from the drop-down list. (If you named your project something else, the prefix will be different in this list.)
4. Select **Customers** from the **Dataset table** list.
5. Change the names of columns in the **Dataset Columns** list individually by using the drop-down list that is available for each column. Create the following mappings:

Source Columns	Dataset Columns
CustomerID	CustID
CompanyName	CompName
ContactName	ContName
ContactTitle	ContTitle

   When you have finished, the **Mappings** dialog box will look like this:



6. Click OK to close the **Table Mappings** dialog box.

Using Controls to Illustrate Mapped Names

In the final step of the walkthrough, you add a **DataGrid** control that illustrates how the mappings are used in the dataset. When you bind the grid to the dataset table, you will see that the dataset table contains the mapped names.

To add and bind a DataGrid control

1. Add a **DataGrid** from the **Windows Forms** tab of the **Toolbox**.
2. Select the **DataGrid** and open the Properties window.
3. Set the following data-binding properties:

   - Set the **DataSource** property to **dsCustomers1**.
   - Set the **DataMember** property to **Customers**.

   The column headings will match those in the schema.

To be able to run the form and see the mapped data in use, you will need to fill the dataset.

To fill the dataset

- Double-click the form (not the control) to create an event handler for the form's **Load** event and add the following line to it:

```
'Visual Basic
OleDbDataAdapter1.Fill(dsCustomers1)

// C#
oleDbDataAdapter1.Fill(dsCustomers1);
```

Finally, you can test the form to see the mapping in action.

To test the form

1. Press **F5** to run the form.
2. When the form is displayed, confirm that the data from the Northwind Customers table is displayed in the grid using the mapped column names.

Next Steps

This walkthrough has provided a brief introduction to table mapping in data adapters. Mapping can be used not just to change column names, but in more sophisticated ways as well, including:

- Map columns from one table to an entirely different column in the dataset.
- Use mapping to limit the number of columns created in a dataset. This is useful if your data adapter reads all the columns in a database table but you only need a few of them in a dataset table.
- Map an expression column in a dataset to a database column. This allows you to calculate values in the dataset and write them to the database.
- Raise errors under various circumstances, including mismatches.

For more information, see Table Mapping in Data Adapters.

Filtering and Sorting in Datasets

After filling a dataset, you will often find it useful to work with different subsets of records in a table, or to view the data in a different order. You can do so by filtering and sorting the data in the dataset. To simplify this process, you can create data views, which provide objects that incorporate filter and sort criteria, and which you can use as the source for data binding.

The topics in this section describe options for filtering and sorting and instructions for performing these actions on data in a dataset.

In This Section

Introduction to Filtering and Sorting in Datasets
Provides an overview of how you can add filtering (selecting) and sorting in a dataset, both by calling data table methods and by using data view.
Adding Data Views to a Form or Component
Describes how to add and configure data views at design time.
Filtering and Sorting Data Using Data Views
Describes how to set data view properties to sort and filter data from a data table.
Filtering And Sorting Directly in Data Tables
Describes how to create lists of sorted or filtered records from a data table, without using a data view.
Working with Records in Data Views
Describes how to edit, insert, and delete records via a data view.
Creating and Working with Data View Managers
Describes how to create a data view manager, which provides centralized access to sorted and filtered views of all the tables in a dataset.

Introduction to Filtering and Sorting in Datasets

After a dataset has been populated, your application might need to view its data in various ways. For example, you might want to view the records in a specific order or see only a subset of the records (that is, filter them). Because the dataset is disconnected from the data source, it is often impractical and resource-intensive to re-execute SQL commands to perform these actions.

Instead, you can use built-in dataset features to filter and sort. You have two options:

- Data tables support a Select method that you can call to filter and sort. The method does not change the contents or order of records in a table; instead, it presents you with a list of records (an array) representing the criteria you specify.
- You can use a data view (DataView object). A data view is an object that acts as a layer on top of the data table, providing a filtered and sorted view of the table's contents. (You can also use a data view manager, which acts like a collection of data views.) A data view is similar to a view in a database, in that it is not a copy of the data. Instead, it is simply a different way of seeing the data in a table.

Both methods provide the same filtering and sorting capabilities. The primary difference is that you can call a data table's **Select** method only in code at run time. Using a data view, on the other hand, provides these advantages:

- You can create and configure the data view at design time, with the option to set its properties at run time as well.
- You can use it in data binding; that is, you can bind controls to it in a designer.
- You can create multiple data views to see the data in a table in different ways. For example, one data view might display data in an Orders table in date order, and another data view might show it in customer order.

> **Note** In some instances, you might not be using a dataset at all. Using a dataset (and filtering and sorting data in it) is an appropriate choice when you want to work with the same set of records while disconnected from the data source. For more information, see Recommendations for Data Access Strategies.

Default Data Views

If you choose to use data views, you can add one to a form or component in much the same way you do other data elements, namely, by dragging it onto a designer and setting its properties. However, even if you do not explicitly add a data view to your form or component, a data view — the default data view — is already available for each table in the dataset. You can access this default data view using a table's DefaultView property, which returns a **DataView** object. You can set the default data view's properties at run time.

For the most part, you can use the default data view as you would any data view. But adding custom data views to your form or component has these advantages:

- You can use multiple data views on a single set of data.
- You can set data view properties at design time. (The default data view is available only at run time.)
- You can assign names to your data views.

Filtering in a Data Table

Using the table's **Select** method or the RowFilter property of a data view, you can filter records in a data table to make available only records you want to work with. This is useful when you want to work with different subsets of the records in a dataset table. To specify filter criteria, you use the same expression syntax used to create column expressions. The filter expression is evaluated as a Boolean expression; if the expression returns **true**, the record is included. A filter expression might look like the following:

```
Price > 10.00
```

In the expression you can reference column values by name (as in the preceding example), property values, and literal values.

Filtering on Row State and Version

A dataset can maintain different versions of records in tables. When records are first filled in, the dataset contains the original version of the record. If you change a record, the dataset maintains a different version — the current version — that reflects the changes. A property on the record indicates whether the record is unmodified, updated, new, or deleted. For more information about row versions and row state, see Introduction to Dataset Updates.

A common use for filters is to specify only the current versions of records in the data table. If records have been changed, there are two versions of a record: The current version reflecting the changes, and the original version representing the record before

any changes were made. Records are also flagged according to their status: new, unchanged, deleted, or modified. A deleted record, for example, still exists in the data table, but its row-state flag has been set to deleted.

If you get all the records in a data table by simply looping through the table's **Rows** collection, you will include records that have been modified, new records, and deleted records. A common filter, therefore, is one that returns only specific versions of a record or records in a certain state.

If you are calling the **Select** method and passing it a filter expression, you can add a parameter indicating what row state or version you want to filter on. If you are using a data view, you can set the RowStateFilter to indicate what version or state of a row you want.

Sorting

Sorting is similar to filtering, in that you specify a sort expression. A typical sort expression is simply the name of the column to sort by. For example, to sort by the OrderDate column, you specify the sort expression `OrderDate`. However, you can sort by the value of any expression, including calculated values. If you call a table's **Select** method, you pass the sort expression as a parameter. If you are using data views, you specify the sort expression as the value of the view's Sort property.

Data View Manager

You can define individual data views that sort or filter the data in each dataset table. If the dataset contains multiple tables, an alternative is to create a data view manager (a DataViewManager object). The data view manager works something like a dataset-wide data view: It provides a single object that manages a collection of data views, each of which is associated with a specific table in a dataset.

A data view manager is particularly useful when you are working with related tables and want to sort or filter child records from a master table. As an example, imagine a dataset containing a Customers table, an Orders table, and a **DataRelation** object that links the two tables. You can use individual data views to sort the Customers table by CompanyName and the Orders table by OrderDate. However, when you use individual data views to sort this way — for example, when you use the relation object's GetChildRecords method to get Orders records — the records won't be sorted. In contrast, if you use a data view manager, they will be.

To use a data view manager, you must create and configure it in code; there is no design-time object that you can add to a form or component. This means that if you want to bind controls to the data view manager, you must also do so in code, as there is no design-time component to bind them to. For more information, see Creating and Working with Data View Managers.

Filtering And Sorting Directly in Data Tables | Working with Records in Data Views

Adding Data Views to a Form or Component

A data view is an object that acts as a layer on top of the data table, providing a filtered and sorted view of the table's contents. (You can also use a data view manager, which acts like a collection of data views.) For more information, see Introduction to Filtering and Sorting in Datasets. You can use design-time tools to add a data view to a form or component.

A common use for data views is to use them as data sources when data binding controls in a form. For more information, see Data Binding and Windows Forms and Data Access in Web Forms Pages.

To add a data view

1. Create a dataset. For more information see Creating Typed Datasets with the Component Designer.
2. Add code to populate the dataset. For more information, see Populating a DataSet from a DataAdapter.
3. From the **Data** tab of the Toolbox, drag a **DataView** item onto the form or component.

   A new data view with the default name DataView1 is added to form or component.

4. If you want to configure the data view at design time (rather than in code at run time), select the data view and use the Properties window to configure the data view. The following table lists commonly used properties of the data view.

   Note You can set all of these properties at run time except the name.

DataView Property	Description
(Name)	The name by which you can refer to the data view in code.
Table	A reference to the table (**DataTable** object) that this is a data view for. You can select a table name from the drop-down list. You must set this property or the view will not contain any records. (However, you can set it at run time.)
Sort	An expression indicating how to order the records represented by the view. (The data table itself is not sorted.) The most typical expression includes the name of a column in the table and, optionally, the qualifier ASC or DESC to indicate the sort direction. However, you can sort by the results of any expression, including calculations. For more information about syntax for sort expressions, see DataColumn.Expression Property.
RowFilter	An expression specifying which records to include in the view. The expression is evaluated as a Boolean expression; if the expression returns **true**, the record is included in the view. An example expression might look like the following: `Price > 10.00` For more information about syntax for filter expressions, see DataColumn.Expression Property.
RowStateFilter	The version of a record to include in the view. The default is **CurrentRows**, which gets a version of the row that includes any changes made to it. For more information about the versions of records in a data table, see Introduction to Dataset Updates
AllowEdit, AllowNew, AllowDelete	Specifies whether the view allows update operations (edit, new, or delete).

Introduction to Filtering and Sorting in Datasets | Filtering and Sorting Data Using Data Views | Working with Records in Data Views

Filtering and Sorting Data Using Data Views

Sorting with a data view allows you to set sort criteria at design time and provides an object you can use for data binding. For an overview, see Introduction to Filtering and Sorting in Datasets.

You can filter and sort using a data view that you have explicitly added to a form or component. Doing this allows you to set filter and sort options at design time. Alternatively, you can use the default data view — called **DefaultView** — that is automatically available for every table in a dataset. When you use the default view, you can specify filter and sort options only in code.

To filter and sort using a data view

1. If you want to set data view options at design time, add a data view to your form or component. For more information, see Adding Data Views to a Form or Component.
2. Set the data view's Sort property using a sort expression. The sort expression can include the names of data table columns or a calculation. If you set the sort expression at run time, the data view reflects the change immediately.

   For more information about syntax for sort expressions, see DataColumn.Expression Property..

3. Set the data view's RowFilter property using a filter expression. The filter expression should evaluate to **true** or **false**, as in this expression:

   ```
   CustomerStatus = 'Active'
   ```

   For more information about syntax for filter expressions, see DataColumn.Expression Property.

   > **Note** If a filter expression contains reserved characters, such as a single quotation mark, those characters must be specified using escape characters. For example, the following expression shows how to use an escape character to include an apostrophe in the expression:
   > CompanyName = 'Margie\'s Travel'
   > .

4. To filter based on a version or state of a record, set the **RowStateFilter** property to a value from the DataViewRowState Enumeration, such as the following:

   ```
   ' Visual Basic
   Dataview1.RowStateFilter = DataViewRowState.CurrentRows

   // C#
   Dataview1.RowStateFilter = DataViewRowState.CurrentRows;
   ```

The following example shows how to set the data view's filter and sort order at run time using the default data view:

```
' Visual Basic
Dataset1.Customers.DefaultView.Sort = "City"

// C#
Dataset1.Customers.DefaultView.Sort = "City";
```

The following example shows how to explicitly add a data view to a form. It checks the values of two radio buttons, and depending on which one is checked, sets a different sort order in the data view. The view filters only the current records. The results are displayed by binding an existing data grid to the data view.

```
' Visual Basic
If radioCity.Checked Then
    DataView1.Sort = "City"
ElseIf radioCompanyName.Checked Then
    DataView1.Sort = "CompanyName"
End If
Dataview1.RowFilter = "CustomerStatus = 'Active'"
Dataview1.RowStateFilter = DataViewRowState.CurrentRows
Me.DataGrid1.DataSource = DataView1
```

```
// C#
if (radioCity.Checked)
{
   DataView1.Sort = "City";
}
else if (radioCompanyName.Checked)
{
   DataView1.Sort = "CompanyName";
}

DataView1.RowFilter = "CustomerStatus = 'Active'";
DataView1.RowStateFilter = DataViewRowState.CurrentRows;
// The following calls a different method to display the
// data view contents.
this.dataGrid1.DataSource = DataView1;
```

Filtering and Sorting Directly in Data Tables

You can filter and sort the contents of a data table directly by calling a table's Select method. This strategy allows you to filter and sort only at run time. If you want to set up criteria for filtering and sorting at design time, and especially if you want to bind controls to the results of filtering or sorting, use a data view. For more information, see Filtering and Sorting Data Using Data Views.

When you sort directly in the data table, you do not reorder the contents of the table. Instead, you work with a result set representing the sorted records.

To filter and sort directly in a data table

- Call the data table's Select method, passing it up to three parameters:

  ```
  datatable.Select(filterExp, sortExp, rowstatevalue)
  ```

  The following table lists the parameter values.

Parameter	Description
filterExp	A filter expression that should evaluate to **true** or **false**.
sortExp	A sort expression. This is typically the name of a table column, but can be any calculated value. **Note** For more information about the syntax of filter and sort expressions, see DataColumn.Expression Property.
rowstatevalue	A value indicating what version or state you want to filter on. The acceptable values for this parameter are members of the DataViewRowState enumeration, such as **DataViewRowState.CurrentRows**. For more information about row state and row version, see Introduction to Dataset Updates.

  You can call the method with only the first or only the first and second parameters. To skip a parameter, pass an empty string as a placeholder.

  The **Select** method returns an array of data rows.

The following example shows how to filter and sort the Customers data table in a dataset called dataSet1. The filter expression selects customers whose status is active. The sort expression causes the results to be sorted by the City column, and the final parameter specifies that you want to see only the current (that is, post-change) versions of the records. The sorted list is displayed in a list box that is assumed to exist on the form.

```
' Visual Basic
Dim filterExp As String = "Status = 'Active'"
Dim sortExp As String = "City"
Dim drarray() As DataRow
Dim i As Integer
drarray = dataSet1.Customers.Select(filterExp, sortExp, DataViewRowState.CurrentRows)
For i = 0 To (drarray.Length - 1)
   listBox1.Items.Add( drarray(i)("City").ToString )
Next

// C#
string filterExp = "Status = 'Active'";
string sortExp = "City";
DataRow[] drarray;
drarray = dataSet1.Customers.Select(filterExp, sortExp, DataViewRowState.CurrentRows);
for (int i=0; i < drarray.Length; i++)
{
   listBox1.Items.Add(drarray[i]["City"].ToString());
}
```

The following example shows how to call the **Select** method to filter only on row state (skipping the filter and sort expressions), returning only deleted records:

```
' Visual Basic
drarray = dataSet1.Customers.Select(Nothing, Nothing, _
   DataViewRowState.Deleted)

// C#
drarray = dataSet1.Customers.Select(null, null,
   DataViewRowState.CurrentRows);
```

Introduction to Filtering and Sorting in Datasets | Filtering and Sorting Data Using Data Views | DataTable.Select Method

Working with Records in Data Views

When you are working with a data view, you can access filtered or sorted records by getting them from the data view instead of directly from the table they are in. You can also update, insert, and delete records via the data view, subject to some restrictions:

- The data view must include enough information about each record to be able to determine where in the data table the record goes. This information can include a primary key or other columns that together provide enough information to uniquely identify a record, such as a customer's name, address, and city.
- The data view's AllowEdit, AllowNew, and AllowDelete properties must be set to **true** for each respective operation.

Finding Records

To find records in a data view

1. Set the data view's **Sort** property to the column or columns you want to search.
2. Call the Find or FindRows method of a data view, passing it the value to look for in the sorted columns.

   - If you want to find a single record, call the **Find** method.

     - or -

   - If you want to find more than one record, use the **FindRows** method. For more information see, Searching a DataView.

The following example shows how to return the index of the found row based on the value in a text box control:

```
' Visual Basic
DataView1.Sort = "CustomerID"
Dim foundIndex as Integer = DataView1.Find(TextBox1.Text)

// C#
dataView1.Sort = "CustomerID";
int foundIndex = dataView1.Find(textBox1.Text);
```

Reading Records

To read records in a data view

- Use an index value to point to the record in the data view that you want to access.

You can access a column by referencing it by name within a data view, as in the following example, which gets the customer name from the first record in the view:

```
' Visual Basic
Dim DataView1 as New DataView(ds.Customers)
Dim cname As String = CType(DataView1(0)("CustomerName"), String)

// C#
DataView dataView1 = new DataView(ds.Customers);
string cname = dataView1[0]["CustomerName"].ToString();
```

The following example shows how to loop through all the records in a data view that points to a Customers table. The example gets the values of three fields (CustomerId, CompanyName, and City) from each record, concatenates all the data into a delimited string, and displays the string in a text box.

```
' Visual Basic
Dim drv As DataRowView
Dim s As String = ""
For Each drv In DataView1
   s &= drv("CustomerID").ToString & "    "
   s &= drv("CompanyName").ToString & "    "
   s &= drv("City").ToString & ControlChars.CrLf
Next
```

```
TextBox1.Text = s

// C#
string s = "";
foreach (DataRowView drv in dataView1)
{
   s += drv["CustomerID"].ToString() + "    ";
   s += drv["CompanyName"].ToString() + "    ";
   s += drv["City"].ToString() + "\n";
}
textBox1.Text = s;
```

Updating Records

To update records via a data view

- In code, use an index value to identify the record to update, and then set the column value by referencing its name.

  Note You cannot edit records via the data view if its **AllowEdit** property is set to **false**.

The following example shows how to identify and update a column.

```
' Visual Basic
DataView1(0)("CompanyName") = "Fabrikam, Inc."

// C#
dataView1[0]["CompanyName"] = "Fabrikam, Inc.";
```

Inserting Records

To insert records via a data view

1. Call the data view's AddNew method, which creates a new record and returns a DataRowView object:

   ```
   ' Visual Basic
   Dim drv As DataRowView
   drv = DataView1.AddNew()

   // C#
   DataRowView drv;
   drv = dataView1.AddNew();
   ```

2. Update the record as you would any data view record.

   Note You cannot insert records via the data view if its **AllowNew** property is set to **false**.

The following example shows how to add a new record to a view, updating three fields in it:

```
' Visual Basic
Dim drv As DataRowView
drv = DataView1.AddNew()
drv("CustomerID") = "AAA"
drv("CompanyName") = "AAFabrikam, Inc."
drv("City") = "Aurora"

// C#
DataRowView drv;
drv = dataView1.AddNew();
drv["CustomerID"] = "AAA";
drv["CompanyName"] = "AAFabrikam, Inc.";
drv["City"] = "Aurora";
```

Deleting Records

To delete records via a data view

- Call the data view's Delete method, passing it the index of the record to delete.

  Note You cannot delete records via the data view if its **AllowDelete** property is set to **false**.

The following example shows how to delete a record:

```
' Visual Basic
DataView1.Delete(0)

// C#
dataView1.Delete(0);
```

Creating and Working with Data View Managers

A data view manager is an object that contains a collection of data views, one for each table in a dataset. The data view manager provides centralized access to sorted and filtered data. This is especially helpful when working with related tables. For an overview, see Introduction to Filtering and Sorting in Datasets.

> **Note** You must create and configure data view managers in code; there is no design-time object for a data view manager.

To create and configure a data view manager

1. Create a dataset. For more information see Creating Typed Datasets with the Component Designer.
2. Add code to populate the dataset. For more information, see Populating a DataSet from a DataAdapter.
3. Create an instance of the DataViewManager class.
4. Set the data view manager's DataSet property to the dataset you created in Step 1.
5. Set sort and filter expressions by accessing individual tables through the DataViewSettings collection.

   > **Note** Accessing a table using the **DataViewSettings** property causes the data view manager to dynamically create a data view for that table. (The data view does not exist until you access it.)

6. If you want to bind controls to the data view manager, set their data-binding properties after configuring the data view manager. For example, in a Windows Form, you can set a control's **DataSource** property to the data view manager and its **DataMember** property to the name of the table (and thus, data view) to bind to.

The following example shows how to create a data view manager and set sort and filter information. The example assumes that there is a dataset called dsCustomersOrders with a Customers and an Orders table. After creating the data view manager, the example binds a data grid to the Titles table available via the data view manager.

```
' Visual Basic
Dim dvm As New DataViewManager()
dvm.DataSet = dsCustomersOrders1
dvm.DataViewSettings("Customers").Sort = "CompanyName"
dvm.DataViewSettings("Orders").Sort = "OrderDate"
Datagrid1.DataSource = dvm
Datagrid1.DataMember = "titles"

// C#
DataViewManager dvm = new DataViewManager();
dvm.DataSet = dsCustomersOrders1;
dvm.DataViewSettings["Customers"].Sort = "CompanyName";
dvm.DataViewSettings["Orders"].Sort = "OrderDate";
dataGrid1.DataSource = dvm;
dataGrid1.DataMember = "titles";
```

Relationships in ADO.NET Datasets

A dataset can contain multiple tables, including tables that have an implicit relationship between them — tables with key fields in common. To take advantage of this implicit relationship, you use an ADO.NET **DataRelation** object. The following topics provide information about ADO.NET **DataRelation** objects, how to create them, and how to use them to work with data in related tables.

In This Section

Introduction to DataRelation Objects
Provides an overview of how datasets allow you to specify relationships between tables and how you can take advantage of these relationships.

Creating DataRelation Objects with the XML Designer
Explains how to use the XML Designer to add a **DataRelation** object to a dataset.

Navigating a Relationship between Tables
Describes how to write code that uses a **DataRelation** object to find related records in a data table.

Introduction to DataRelation Objects

There are many times when your application needs to work with related tables. Although a dataset contains tables and columns as in a database, it does not inherently include a database's ability to relate tables. However, you can create DataRelation objects that establish a relationship between a parent (master) and a child (detail) table based on a common key.

For example, a dataset containing sales data might have a Customers table and an Orders table. Even if the tables contain a key in common (in this example, perhaps CustomerID), the dataset itself does not keep track of the records in one table that relate to those in another. But you can create a **DataRelation** object that references the parent and child tables (and their keys), and then use the object to work with the related tables.

The **DataRelation** object can perform two functions:

- It can make available the records related to a record you are working with. It provides child records if you are in a parent record, and a parent record if you are working with a child record.
- It can enforce constraints for referential integrity, such as deleting related child records when you delete a parent record.

It is important to understand the difference between a true join and the function of a **DataRelation** object. In a true join, records are taken from parent and child tables and put into a single, flat recordset. When you use a **DataRelation** object, no new recordset is created. Instead, the relation tracks the relationship between tables and keeps parent and child records in synch.

Accessing Related Records

If tables in a dataset have a logical relationship, a **DataRelation** object can make available to you the related records in another table. An example might be a dataset containing a customer database with the tables Customers (with the primary key CustomerID) and Orders (with a foreign key CustomerID). You can create a **DataRelation** object whose properties are set to reflect these keys.

You can then use the **DataRelation** object to get related records. The process is indirect, in that you do not join tables. Instead, you call the GetChildRows method of a data row in the parent table, passing to it the **DataRelation** object that defines the parent/child relationship. The method returns an array of related child records.

The following code illustrates a simple example of getting related records. In this example, the array `drarray` is set to the child records of the first row in the Customers table.

```
' Visual Basic
Dim RowCtr As Integer
' Dim an array of datarows to hold the child records.
Dim drarray() As DataRow
' GetChildRows gets related rows. It is a method on the datatable, and
' takes a DataRelation name as a string.
RowCtr = 0
drarray = dsCustomersOrders1.Customers(RowCtr).GetChildRows("CustomersOrders")

// C#
int rowCtr;
// Declare an array of datarows to hold the child records.
DataRow[] drarray;
// GetChildRows gets related rows. It is a method on the datatable, and
// takes either DataRelation object name as a string.
rowCtr = 0;
drarray = dsCustomersOrders1.Customers[rowCtr].GetChildRows("CustomersOrders");
```

Similarly, you can get the parent row of a given child record by calling the GetParentRow method of a data row in the child table. In that case, the method does not return an array, but a single data row. For more information, see Navigating a Relationship between Tables.

DataRelation Objects and Constraints

A **DataRelation** object is also used to create and enforce the following constraints:

- A unique constraint, which guarantees that a column in the table contains no duplicates.
- A foreign-key constraint, which can be used to maintain referential integrity between a parent and child table in a dataset.

Constraints that you specify in a **DataRelation** object are implemented by automatically creating appropriate objects or setting

properties. If you create foreign-key constraint using the **DataRelation** object, instances of the ForeignKeyConstraint class are added to the data relation's ChildKeyConstraint property.

A unique constraint is implemented either by simply setting the Unique property of a data column to **true** or by adding an instance of the UniqueConstraint class to the **DataRelation** object's ParentKeyConstraint.

As part of the foreign-key constraint, you can specify referential integrity rules that are applied at three points:

- when a parent record is updated
- when a parent record is deleted
- when a change is accepted or rejected

The rules you can make are specified in the Rule enumeration and are listed in the following table.

Foreign-key constraint rule	**Action**
Cascade	The change (update or delete) made to the parent record is made in related records in the child table as well.
SetNull	Child records are not deleted, but the foreign key in the child records is set to **DBNull**. With this setting, child records can be left as "orphans" — that is, they have no relationship to parent records. **Note** Using this rule can result in invalid data in the child table.
SetDefault	The foreign key in the related child records is set to its default value (as established by the column's DefaultValue property).
None	No change is made to related child records. With this setting, child records can end up containing references to invalid parent records.
Default	The default value is **Cascade**.

For more information about updates in dataset tables, see Dataset Updates in Visual Studio .NET.

Constraint-only Relations

When creating a **DataRelation** object, you have the option of specifying that the relation will be used only to enforce constraints — that is, it will not also be used to access related records. This option allows you to generate a dataset that is slightly more efficient and that contains fewer methods than one with the related-records capability. However, you will not be able to access related records.

Creating DataRelation Objects with the XML Designer

DataRelation objects are part of a dataset's structure, along with the tables and columns defined in the dataset. For typed datasets, therefore, **DataRelation** objects are defined in the dataset schema. You create **DataRelation** objects in a dataset using the XML Designer. You do not have to know XML or the schema format in order to do so.

To create a DataRelation object in a dataset

1. If it does not already exist, create the schema for the dataset. For more information, see Visual Studio Tools for Creating Datasets.
2. In Solution Explorer, double-click the XML Schema (.xsd) file to open it in the XML Designer.

   The schema is opened in **Schema** view, with each table displayed in a gridlike control.

3. From the **Data** tab of the Toolbox, drag a **Relation** object onto the child table.

   The **Relation (KeyRef) Editor** dialog box opens.

4. If you want to assign a new name to the **DataRelation** object, overwrite the value in the **Name** box.
5. Make sure that the **Parent Element** selector is set to the name of the parent table and the **Child Element** selector to the name of the child table for which you want to create the **DataRelation** object.
6. From the **Key** list, choose the key in the parent table that you want to create a **DataRelation** object for.

   > **Note** The items presented in the **Key** list are not the names of the primary key columns. Instead, they are schema elements that can reference any column with a unique constraint (including, but not limited to, the primary key). There can be multiple key elements for a table, even for a table with a single-part primary key. For more information, see Introduction to Data Access with ADO.NET.

7. In the **Fields** grid, make sure that the columns for the parent table primary key (**PK Field**) and the child table foreign key (**FK Field**) column are set appropriately. If necessary, you can overwrite the names of the columns in the grid, or you can type in the names of additional columns used to define the parent/child relationship.
8. If you want to create a relation used only to enforce constraints (not used to get related records from a child or parent table), check **Constraint only**.

   Creating a constraint-only relation results in a slightly more efficient dataset with fewer methods in it. However, you will not be able to access related records.

9. If you want the dataset to enforce referential integrity during updates and deletes, check the **Enforce Constraints** box and then select an enforcement rule from the lists under **Update Rule** and **Delete Rule**. For more information about constraints and what each setting means, see Introduction to DataRelation Objects.

   > **Note** If you do not check this box, the **DataRelation** object allows you to get related records from each table, but does not perform update operations on the related table in order to keep the tables synchronized.

10. Click **OK** to create the **DataRelation** object.

    The XML Designer draws a relationship line between the parent and child table, with the relation object represented as a gray square.

To edit a relation object

- In **Design** view of the XML Designer, right-click the relation object (the gray square) and choose **Edit Relation**.

  The **Relation (KeyRef) Editor** dialog box opens, displaying information about the current relation object.

To remove a relation object

- In **Design** view of the XML Designer, click the relation object (the gray square) to select it, and then from the **Edit** menu, choose **Delete**.

Performing Database Operations Directly

In many situations, you will design your data access strategy around using a dataset (an in-memory cache of data) and data adapters to fill the dataset and perform updates. In other situations, however, you might find it useful to bypass datasets and communicate directly with the data source. These situations include:

- Performing queries on data intended to be read-only in your application. This might include executing a command that performs a database lookup.
- Designing data access in ASP.NET Web applications, which under various circumstances might not benefit from using a dataset.
- Executing a query that returns only a single value, such as a calculation or the result of an aggregate function.
- Creating and modifying database structures, such as tables and stored procedures.

When you are creating tables and stored procedures or otherwise executing logic that does not return a result set, you cannot use a dataset; instead, you execute data commands directly. In the other situations, using data commands is an alternative to using data adapters and a dataset, and you can choose between the alternating ways to access data.

The following topics provide information on what data commands are and when and how to use them.

In This Section

Introduction to DataCommand Objects in Visual Studio
Provides an overview of data command objects and how to work with them.
Recommendations for Data Access Strategies
Provides information on choosing between datasets and data commands for data access.
Working with Data Commands: High-Level Process
Explains, at a high level, the steps involved in creating data commands and executing them.
Adding Data Commands to a Form or Component
Explains how to add a data command object to a form or component in Visual Studio.
Setting and Getting Data Command Parameters
Explains how to use the **Parameters** collection to pass data to commands and read return values after the command has been executed.
Executing a Data Command that Returns a Result Set
Provides instructions on how to execute a data command using a data reader that returns one or more records.
Executing Updates or Database Commands using a Data Command
Describes how to execute Update, Insert, and Delete statements directly against the database, and how to issue database definition language (DDL) commands.
Executing a Data Command that Returns a Single Value
Provides instructions on how to execute a command that returns a single value, such as a command that performs a lookup or calculates a value.

Adding a Launch Condition for Microsoft Data Access Components

Describes how to check that the correct version of the ADO.NET data access components is available when you install your application.

Recommendations for Data Access Strategies

ADO.NET assumes a model for data access in which you open a connection, get data or perform an operation, and then close the connection. ADO.NET provides two basic strategies for how you work with this model. One model is store data in a dataset, which is an in-memory cache of records you can work with while disconnected from the data source. To use a dataset, you create an instance of it and then use a data adapter to fill it from the data source. You then work with the data in the dataset — for example, by binding controls to dataset members. For more information, see Introduction to Datasets.

An alternative strategy is to perform operations directly against the database. In this model, you use a data command object that includes an SQL statement or a reference to a stored procedure. You can then open a connection, execute the command to perform the operation, and then close the connection. If the command returns a result set — that is, if the command performs a Select statement — you can fetch the data using a data reader, which acts like a highly efficient read-only cursor. The data reader can then act as a source for data binding. For more information, see Introduction to DataCommand Objects in Visual Studio.

Each strategy has specific advantages, as detailed in the sections below. You should choose a strategy based on what your data-access requirements are.

> **Note** When you deploy an application that includes Visual Studio data-access components, you must make sure that the user installing the application has version 2.7 or later of the Microsoft Data Access Components (MDAC). For more information, see Adding a Launch Condition for Microsoft Data Access Components.

Storing Data in Datasets

A common model for data access in Visual Studio .NET applications is to store data in datasets and use a data adapter to read and write data in the database. (A .NET application is one that uses the .NET Framework: the common language runtime and the managed classes.) The advantages of the dataset model are:

- **Working with multiple tables** A dataset can contain multiple tables of results, which it maintains as discrete objects. You can work with the tables individually or navigate between them as parent-child tables.
- **Manipulating data from multiple sources** The tables in a dataset can represent data from many different sources (for example, from different databases, from XML files, spreadsheets, and so on, all in the same dataset). Once the data is in the dataset, you can manipulate it and relate it in a homogeneous format as if it had come from a single source.
- **Moving data between tiers in a distributed application** By keeping data in a dataset, you can easily move it between the presentation tier, business tier, and data tier of your applications.
- **Data exchange with other applications** A dataset provides a powerful way to exchange with other components of your application and with other applications. Datasets include extensive support for features such as serializing data as XML and reading and writing XML Schemas.
- **Data binding** If you are working with forms, it is usually easier to bind controls to data in a dataset than it is to programmatically load data values into the control after executing a command.
- **Maintaining records for reuse** A dataset allows you to work with the same records repeatedly without requerying the database. Using dataset facilities, you can filter and sort records, and you can use the dataset as a source of data if you are paging.
- **Ease of programming** When you work with a dataset, you can generate a class file that represents its structure as objects (for example, a Customers table in the dataset can be accessed as the *dataset*.Customers object). This makes it easier, clearer, and less error-prone to program with, and is supported by Visual Studio tools such as IntelliSense, the Data Adapter Configuration wizard, and so on.

Performing Database Operations Directly

Alternatively, you can interact with the database directly. In this model, you use a data command object that includes an SQL statement or a reference to a stored procedure. You can then execute the command to perform the operation. If the command returns a result set — that is, if the command performs a Select statement — you can fetch the data using a data reader, which acts like a highly efficient read-only cursor.

> **Security Note** When using data commands with a CommandType property set to **Text**, carefully check information that is sent from a client before passing it to your database. Malicious users might try to send (inject) modified or additional SQL statements in an effort to gain unauthorized access or damage the database. Before you transfer user input to a database, you should always verify that the information is valid. A best practice is to always use parameterized queries or stored procedures when possible.

Performing database operations directly has specific advantages, which include:

- **Extra functionality** As noted, there are some operations, such as executing DDL commands, that you can only accomplish by executing data commands.
- **More control over execution** By using commands (and a data reader, if you are reading data), you get more direct control over how and when an SQL statement or stored procedure is executed and what becomes of the results or return values.
- **Less overhead** By reading and writing directly to the database, you can bypass storing data in a dataset. Because the dataset requires memory, you can reduce some overhead in your application. This is especially true in situations where you intend to use the data only once, such as displaying search results in a Web page. In that case, creating and filling a dataset might be an unnecessary step in displaying the data.
- **Less programming in some instances** In a few instances, particularly Web applications, there is some extra programming required to save the state of a dataset. For example, in Web Forms pages, the page is recreated with each round trip; unless you add programming to save and restore a dataset, it, too, is discarded and recreated with each round trip. If you use a data reader to read directly from the database, you avoid the extra steps required to manage the dataset.

Because of the stateless nature of Web applications and the corresponding issues associated with storing datasets, it is sometimes more practical in Web applications to work directly against the database. For more information, see Introduction to Data Access in Web Forms Pages.

Recommendations for Accessing Data

The following sections provide recommendations for which data-access strategy to use with specific types of applications.

Web Forms

In general, use data commands; to fetch data, use a data reader. Because Web Forms pages and their controls and components are recreated each time the page makes a round trip, it often is not efficient to create and fill a dataset each time, unless you also intend to cache it between round trips.

Use dataset under the following circumstances:

- You want to work with multiple separate tables or tables from different data sources.
- You are exchanging data with another application or a component such as an XML Web service.
- You need to perform extensive processing with each record you get from the database. If you use a data command and data reader, processing each record as you read it can result in the connection being held open for a long period, which in turn can affect the performance and scalability of your application.
- If your data processing involves interdependent records (for example, looking up information in related records).
- If you want to perform XML operations such as XSLT transformations on the data.
- If you prefer the ease of programming provided by datasets.

For more information, see Web Data Access Strategy Recommendations.

XML Web Services

XML Web services are ASP.NET Web applications, and therefore use the same model as Web Forms pages: the XML Web service is created and discarded each time a call is made to it. This suggests that the data-access model for an XML Web service is largely the same as it is for Web Forms. However, XML Web services are often middle-tier objects, and an important part of their purpose is often to exchange data with other applications across the Web.

Use a dataset if:

- Your XML Web service sends and receives data — for example, sending it as the return value of a method and receiving it as a method argument. This is a fundamental choice in XML Web services; even if there are other reasons you might consider using a data command, data exchange with other components almost always means that you should use a dataset.
- For any of the reasons listed above for Web Forms.

Use a data command (and if appropriate, a data reader) under the following circumstances:

- The XML Web service is retrieving a scalar value.
- The XML Web service is performing a non-query operation, such as a DDL command.
- The XML Web service is calling a stored procedure to execute logic within the database.

Windows Forms

In general, in a Windows Form, use a dataset. Windows Forms are typically used on rich clients where the form is not created and discarded (along with its data) with each user operation, as with Web Forms. Windows Forms applications also traditionally offer data-access scenarios that benefit from maintaining a cache of records, such as displaying records one by one in the form.

Specifically, use dataset under the following circumstances:

- If you are working with the same records repeatedly, such as allowing a user to navigate between records.
- If you are using the Windows Forms data-binding architecture, which is specifically designed to work with datasets.
- For any of the other reasons listed under Web Forms above.

Use a data command (and if appropriate, a data reader) under the following circumstances:

- If you are getting a scalar value from the database
- If you are performing a non-query operation, such as a DDL command.
- If you are getting read-only data to display in a form — for example, creating a report. Stated differently, if there is no need to keep the data available after accessing it, use a data command.

Working with Data Commands: High-Level Process | Executing a Command | Introduction to Dataset Updates

Working with Data Commands: High-Level Process

ADO.NET data commands give you the ability to execute commands directly against a database or other data source, without needing a dataset or data adapter. For more information, see Introduction to DataCommand Objects in Visual Studio.

> **Security Note** When using data commands with a CommandType property set to **Text**, carefully check information that is sent from a client before passing it to your database. Malicious users might try to send (inject) modified or additional SQL statements in an effort to gain unauthorized access or damage the database. Before you transfer user input to a database, you should always verify that the information is valid; best practice is to always use parameterized queries or stored procedures when possible.

To use a data command in Visual Studio, you perform a set of steps, some at design time and others at run time, typically using code.

To work with data commands

1. At design time, add a data command to your form or component and set:

   - Its SQL command or stored procedure.
   - Any parameters that the command requires.

   For more information, see Adding Data Commands to a Form or Component.

   > **Note** As with all data components, you can also create and configure a data command programmatically at run time. For more information, see Executing a Command.

2. At run time, set any parameter values that you want to pass to the data command. You often get parameter values from information that the user enters into a form or that is passed from another component. For more information, see Setting and Getting Data Command Parameters.
3. Execute the command. This runs the SQL command or stored procedure associated with the command. The exact command you use to execute the data command depends on what you expect the command to return: a result set, a scalar value, a count of affected value, or XML data.
4. Read the return value or values from the data command. As with executing the command, the way you read results vary depending on what type of command you executed and what it returns.

   For more information about different ways to execute commands and get their results, see the following topics:

   - Executing a Data Command that Returns a Result Set
   - Executing Updates or Database Commands using a Data Command
   - Executing a Data Command that Returns a Single Value
   - Obtaining Data as XML from SQL Server

Adding Data Commands to a Form or Component

ADO.NET data commands give you the ability to execute commands directly against a database or other data source, without needing a dataset or data adapter. For more information, see Introduction to DataCommand Objects in Visual Studio.

Before executing a data command, you add an instance of a command object to your form or component and configure it. Visual Studio includes tools to help you do this at design time.

> **Security Note** When using data commands with a CommandType property set to **Text**, carefully check information that is sent from a client before passing it to your database. Malicious users might try to send (inject) modified or additional SQL statements in an effort to gain unauthorized access or damage the database. Before you transfer user input to a database, you should always verify that the information is valid; best practice is to always use parameterized queries or stored procedures when possible. For more information, see Security Considerations regarding SQL Statements.

To add a data command to a form or component

1. If you do not already have a connection object available on the form or component, add one. For more information, see Creating ADO.NET Connection Objects.
2. From the **Data** tab of the Toolbox, drag an OleDbCommand, SqlCommand, OdbcCommand, or OracleCommand object onto your form or component.

   > **Note** Data adapters, data connections, data commands, and data readers are the components that make up a .NET Framework data provider. Microsoft and third-party providers can make available other .NET Framework data providers that can be integrated into Visual Studio. For more information, see .NET Framework Data Providers.

3. Set the following properties for the data command.

Property	Description
(Name)	The name by which you want to refer to the command in code.
Connection	A reference to a connection object that the command will use to communicate with the database. You can select an existing connection from the drop-down list.
CommandType	A value specified by the CommandType enumeration indicating what type of command you want to execute: • **Text** An SQL statement. • **StoredProcedure** A stored procedure. • **TableDirect** A way of fetching the entire contents of a table. (**TableDirect** is only supported by the .NET Framework Data Provider for OLE DB.)
CommandText	The command to execute. The exact text you specify depends on the value of the **CommandType** property: • **Text** Enter the actual SQL statement to execute. • **StoredProcedure** Enter the name of the stored procedure. • **TableDirect** Enter the name of the table to fetch. (**TableDirect** is only supported by the .NET Framework Data Provider for OLE DB.)
Parameters	A collection of parameter objects of type (OleDbParameter, SqlParameter, OdbcParameter, or OracleParameter). You can pass data to the command by setting properties of individual parameters. For more information on configuring parameters, see Configuring Parameters for Data Adapters. For more information about passing and receiving parameter values, see Setting and Getting Data Command Parameters.

Next Steps

After you have added a data command, you need to execute it.

If you want to return a ...	See
Result set	Executing a Data Command that Returns a Result Set
Count of affected records	Executing Updates or Database Commands Using a Data Command
Scalar value	Executing a Data Command that Returns a Single Value

Result set as XML	Obtaining Data as XML from SQL Server

See Also

Introduction to DataCommand Objects in Visual Studio | Working with Data Commands: High-Level Process | Parameters in Data-Adapter Commands | Configuring Parameters for Data Adapters | Setting and Getting Data Command Parameters

Setting and Getting Data Command Parameters

If you are using data commands directly to execute commands against a database, the SQL statements or stored procedures you are executing often require parameters. For example, a simple Update statement that requires parameters might look like the following:

```
UPDATE Employees
SET LastName = @LastName, FirstName = @FirstName, BirthDate = @BirthDate
WHERE (EmployeeID = @Emp_id)
```

When this statement is executed, you must provide values for all the parameters (@LastName, @FirstName, @BirthDate, and @Emp_id). To do so, you use parameter objects. Data commands support a **Parameters** collection that contains a set of objects of type OleDbParameter , SqlParameter, OdbcParameter or OracleParameter class. There is one parameter object in the collection for each parameter you need to pass. In addition, if you are calling a stored procedure, you might need an additional parameter to accept the procedure's return value.

> **Note** For Oracle, when using named parameters in an SQL statement or stored procedure, you must precede the parameter name with a colon (:). However, when referring to a named parameter elsewhere in your code (for example, when calling the **Add** method), do not precede the named parameter with a colon (:). The data provider supplies the colon automatically.

> **Note** If you are using a dataset, you typically do not execute data commands directly. Instead, you use adapter-specific ways to set parameters. For more information, see Using Parameters with a DataAdapter.

You can configure a command's **Parameters** collection using the Properties window or in code. For more information about using the Properties window, see Configuring Parameters for Data Adapters. For an example of how to create and configure parameters programmatically, see Using Stored Procedures with a Command.

> **Tip** It is a good idea to give names to your parameter objects so that you can reference them in code easily. Although you can reference a parameter object using its index value in the **Parameters** collection, it is clearer and less error-prone to refer to it by name.

Before you execute a command, you must set a value for every parameter in the command.

To set a parameter value

- For each parameter in the command's **Parameters** collection, set its **Value** property to the value to pass.

  The following example shows how to set parameters before executing a command that references a stored procedure. The sample assumes that you have already configured the **Parameters** collection with three parameters named au_id, au_lname, and au_fname. The individual parameters are set by name to make it clear which parameter is being set.

```
' Visual Basic
' The CommandText and CommandType properties can be set
' in the Properties window but are shown here for completeness.
With OleDbCommand1
   .CommandText = "UpdateAuthor"
   .CommandType = System.Data.CommandType.StoredProcedure
   .Parameters("au_id").Value = listAuthorID.Text
   .Parameters("au_lname").Value = txtAuthorLName.Text
   .Parameters("au_fname").Value = txtAuthorFName.Text
End With
OleDbConnection1.Open()
OleDbCommand1.ExecuteNonQuery()
OleDbConnection1.Close()

// C#
// The CommandText and CommandType properties can be set
// in the Properties window but are shown here for completeness.
OleDbCommand1.CommandText = "UpdateAuthor";
OleDbCommand1.CommandType = System.Data.CommandType.StoredProcedure;
```

```
OleDbCommand1.Parameters["au_id"].Value = listAuthorID.Text;
OleDbCommand1.Parameters["au_lname"].Value = txtAuthorLName.Text;
OleDbCommand1.Parameters["au_fname"].Value = txtAuthorFName.Text;
OleDbConnection1.Open();
OleDbCommand1.ExecuteNonQuery();
OleDbConnection1.Close();
```

Getting Return Values

Stored procedures often pass values back to the application that called them. They can do so by passing the value using a parameter or by defining and passing a return value.

To get values returned by procedures

1. Create parameters whose **Direction** property is set to **Output** or **InputOutput** (if the parameter is used in the procedure to both receive and send values). Make sure the data type of the parameter matches the expected return value.
2. After executing the procedure, read the **Value** property of the parameter being passed back.

To get a procedure's return value

1. Create a parameter and set its **Direction** property is set to **ReturnValue**.

   Note The parameter object for the return value must be the first item in the **Parameters** collection.

2. Make sure the parameter's data type matches the expected return value.

   Note Update, Insert, and Delete SQL statements return an integer value indicating the number of records affected by the statement. You can get this value as the return value of the **ExecuteNonQuery** method. For more information, see Executing Updates or Database Commands using a Data Command.

The following example shows how to get the return value of a stored procedure called CountAuthors. In this case, it is assumed that the first parameter in the command's **Parameters** collection is named "retvalue" and that is configured with a direction of **ReturnValue**.

```
' Visual Basic
Dim cntAffectedRecords As Integer

Executing a Data Command that Returns a Result Set

You can use a data command to execute a database procedure that returns a read-only result set — that is, you can execute a SQL Select statement or a stored procedure that contains a Select statement. This is similar to what happens when you fill a dataset using a data adapter, except that the result set is returned directly to you.

If you don't have other reasons to use a dataset (for example, you want to share the data with another component or application), it can be faster to use a data command to get a result set directly rather than load it into the dataset. For more information on the relative advantages of datasets versus data commands, see Recommendations for Data Access Strategies.

You can return zero or more records using a data command. You might therefore use a data command for the following:

- To return a set of records that you fill into a control on a form. This is especially useful in Web Forms pages, where you often creating read-only listings (such as search results or inventory lists).
- To return a single record, which you pinpoint by passing parameters to the command that identify the record by ID or other unique value. You might pass an ID to a command to get back a corresponding record, or you might be filling a single record into a data view so you can bind a set of form controls to the data view.
- To execute a command that returns catalog information from a database.

A result set is returned to you in a data reader (an object of type OleDbDataReader, SqlDataReader, OdbcDataReader, or OracleDataReader). You can then loop through this object, extracting individual records from the result set. Because the data reader provides forward-only, read-only access to the data, it is very fast.

To execute a command that returns a result set

1. Add a data command to your form or component. For more information, see Adding Data Commands to a Form or Component.
2. Set the data command object's **CommandText** property to an SQL statement or the name of a stored procedure that returns a result set.
3. Set the **CommandType** property to **CommandType.Text** (for a statement) or **CommandType.StoredProcedure** (for a stored procedure). These values are defined in the CommandType enumeration.
4. If the command takes parameters, set them. For more information, see Setting and Getting Data Command Parameters.
5. Create a data reader object as an instance of either the OleDbDataReader, SqlDataReader, OdbcDataReader, or OracleDataReader class.
6. Open the connection associated with the data command.
7. Call the command's **ExecuteReader** method, setting the result to the data reader you created in Step 5.

   Tip The **ExecuteReader** method allows you to pass a parameter indicating command behavior, including options to close the connection immediately, return only a single record, and return keys only. For more information, see OleDbCommand.ExecuteReader Method (CommandBehavior) SqlCommand.ExecuteReader Method (CommandBehavior), OdbcCommand.ExecuteReader Method (CommandBehavior), or OracleCommand.ExecuteReader Method (CommandBehavior).

8. Loop through the data reader using its **Read** method until the method returns false.
9. Close the reader.
10. If you did not do so in executing the **ExecuteReader** method, close the connection.

The following example shows how to read the records in the Authors table of the SQL Server pubs database. The example uses the command type of **TableDirect** and specifies the name of the Authors table as the command text. (Both of these settings can be made in the Properties window, but are shown here for completeness.) When the ExecuteReader method has been called, the example loops through the data reader and builds up a delimited string of author information that it displays in a text box.

Note In the example, column information is extracted by referring to its column name in the data reader. You can optimize access by using more efficient ways to get the column information. For more information, see Retrieving Data Using the DataReader.

```
' Visual Basic
Dim dreader As System.Data.OleDb.OleDbDataReader
OleDbCommand1.CommandText = "authors"
OleDbCommand1.CommandType = CommandType.TableDirect
```

```
OleDbConnection1.Open()
dreader = OleDbCommand1.ExecuteReader(CommandBehavior.CloseConnection)
Dim s As String = ""
While dreader.Read()
   s &= dreader("au_id").ToString() _
     & vbTab & dreader("au_fname").ToString() _
     & " " & dreader("au_lname").ToString & ControlChars.CrLf
End While
TextBox1.Text = s
dreader.Close()

// C#
System.Data.OleDb.OleDbDataReader dreader;
OleDbCommand1.CommandText = "authors";
OleDbCommand1.CommandType = CommandType.TableDirect;
OleDbConnection1.Open();
dreader = OleDbCommand1.ExecuteReader(CommandBehavior.CloseConnection);
string s = "";
while (dreader.Read())
{
   s += dreader["au_id"].ToString() + "\t"
     + dreader["au_fname"].ToString() + " "
     + dreader["au_lname"].ToString() + "\n";
}
TextBox1.Text = s;
dreader.Close();
```

The following example shows two ways to use a data reader to get data. The first part is similar to the previous example, but it uses a data reader to load a **ListBox** control in a Windows Form with just the **author_id** column from the authors table.

The second part is a handler for the list box control's **SelectedIndexChanged** event. The method uses the au_id value that the user has selected as the parameter for a SQL Select statement written to return only one record (by selecting on the primary key). Because the data reader is expected to return only one record, it is not in a loop; instead, its **Read** method is called only one. (The example does check that there is at least one record by calling the **Read** method in an if statement.)

The two event handlers use different data commands; the first one takes no parameters, and the second one takes a single parameter for the author id.

```
' Visual Basic
Private Sub btnLoadListBox_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles btnLoadListBox.Click
   ' This method fills a ListBox control with author ids.
   Dim dreader As System.Data.OleDb.OleDbDataReader
   OleDbCommand1.CommandText = "authors"
   OleDbCommand1.CommandType = CommandType.TableDirect
   OleDbConnection1.Open()
   dreader = OleDbCommand1.ExecuteReader()
   While dreader.Read()
      ListBox1.Items.Add(dreader("au_id"))
   End While
   dreader.Close()
   OleDbConnection1.Close()
End Sub

Private Sub ListBox1_SelectedIndexChanged(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles ListBox1.SelectedIndexChanged
   Dim dreader As System.Data.OleDb.OleDbDataReader
   ' The following two properties can be set in the Properties window
   ' but are shown here for completeness.
   OleDbCommand2.CommandText = _
      "select au_id, au_lname, au_fname from authors where au_id = ?"
   OleDbCommand2.CommandType = CommandType.Text
   OleDbCommand2.Parameters("au_id").Value = ListBox1.Text
   OleDbConnection1.Open()
   dreader = OleDbCommand2.ExecuteReader()
   If dreader.Read() Then
      txtAuthorID.Text = dreader("au_id").ToString()
```

```
        txtAuthorLastName.Text = dreader("au_lname").ToString()
        txtAuthorFirstName.Text = dreader("au_fname").ToString()
    End If
    dreader.Close()
    OleDbConnection1.Close()
End Sub

// C#
private void btnLoadListBox_Click(object sender, System.EventArgs e)
{
    // This method fills a ListBox control with author ids.
    System.Data.OleDb.OleDbDataReader dreader;
    OleDbCommand1.CommandText = "authors";
    OleDbCommand1.CommandType = CommandType.TableDirect;
    OleDbConnection1.Open();
    dreader = OleDbCommand1.ExecuteReader();
    while( dreader.Read())
    {
        ListBox1.Items.Add(dreader["au_id"]);
    }

    dreader.Close();
    OleDbConnection1.Close();
    Button6.Enabled = true;
}

private void ListBox1_SelectedIndexChanged(object sender,
System.EventArgs e)
{
    System.Data.OleDb.OleDbDataReader dreader;
    // The following two properties can be set in the Properties window
    // but are shown here for completeness.
    OleDbCommand2.CommandText =
        "select au_id, au_lname, au_fname from authors where au_id = ?";
    OleDbCommand2.CommandType = CommandType.Text;
    OleDbCommand2.Parameters["au_id"].Value = ListBox1.Text;
    OleDbConnection1.Open();
    dreader = OleDbCommand2.ExecuteReader();
    if (dreader.Read())
    {
        txtAuthorID.Text = dreader["au_id"].ToString();
        txtAuthorLastName.Text = dreader["au_lname"].ToString();
        txtAuthorFirstName.Text = dreader["au_fname"].ToString();
    }
    dreader.Close();
    OleDbConnection1.Close();
}
```

Executing Updates or Database Commands using a Data Command

Some types of data commands that you can execute against a database do not return any values except a value indicating the success of the command. These types of commands include:

- Database definition (DDL) commands that you use to create and manage database structures such as tables and stored procedures.
- Update commands (Update, Insert, and Delete statements).

You must use database commands to execute DDL operations; there is no other way to perform these tasks in ADO.NET.

If you are using a dataset, you do not need to use a separate data command to execute database updates. Instead, you use the data adapter to update the database. For more information, see Dataset Updates in Visual Studio .NET. However, if you are not using a dataset, you can send update commands directly to the database. For more information on the relative advantages of datasets versus data commands, see Recommendations for Data Access Strategies.

With both types of commands, the command returns an integer indicating the success of the operation. The return value differs according to whether you are updating records or issuing a DDL command:

- If you are creating or modifying database structures, the return value is -1 if the operation was successful.
- If you are updating records, the return value indicates the number of records affected by the operation.

In either case, if the operation fails, the command returns zero.

To execute a command to update a database

1. Add a data command to your form or component and configure it with the SQL statement or stored procedure to execute. For more information, see Adding Data Commands to a Form or Component.
2. If the command takes parameters, configure them. For more information, see Configuring Parameters for Data Adapters.
3. If there are parameters, add code to set their values. For more information, see Setting and Getting Data Command Parameters.
4. Add code to open the connection associated with the data command.
5. Call the command's ExecuteNonQuery Method, setting the result to an integer.

   Note Although the method returns only a single integer value, a stored procedure you call might return values using the command's Parameters collection. For more information about working with parameters, see Setting and Getting Data Command Parameters.

6. Close the connection.

The following example shows how to create a new table in a database. The example assumes that you have already added a data command and a connection to the form or component and configured the command to use that connection. The code sets the CommandText Property to a SQL Server Create Table statement that creates a two-column table of lookup codes. The method returns -1 if the table is created successfully.

```
' Visual Basic
Dim newtablecmd As String
Dim cmdresults As Integer
newtablecmd = "CREATE TABLE LookupCodes (code_id  smallint IDENTITY(1,1) PRIMARY KEY CLUSTERE
D, code_desc  varchar(50) NOT NULL)"

' The following two property settings can also be set
' in the Properties window, but are shown here for completeness.
OleDbCommand1.CommandType = CommandType.Text
OleDbCommand1.CommandText = newtablecmd

' The connection must be open before you can execute a command.
OleDbConnection1.Open()
cmdresults = OleDbCommand1.ExecuteNonQuery()
OleDbConnection1.Close()
MessageBox.Show("After creating the table, results = " & cmdresults.ToString)
```

```
// C#
string newtablecmd;
int cmdresults;
newtablecmd = "CREATE TABLE LookupCodes (code_id  smallint IDENTITY(1,1) PRIMARY KEY CLUSTERE
D, code_desc  varchar(50) NOT NULL)";

// The following two property settings can also be done
// in the Properties window, but are shown here for completeness.
OleDbCommand1.CommandType = CommandType.Text;
OleDbCommand1.CommandText = newtablecmd;

// The connection must be open before you can execute a command.
OleDbConnection1.Open();
cmdresults = OleDbCommand1.ExecuteNonQuery();
OleDbConnection1.Close();
MessageBox.Show("After creating the table, results = " + cmdresults.ToString());
```

The following example shows how to use a data command to update a database by inserting a new record into the Authors table of the SQL Server Pubs database. In this instance, the command calls a stored procedure named "NewAuthor" that is assumed to contain an Insert Into statement with nine values for the new author record. The data command OleDbCommand2 has already been configured to have a **Parameters** collection with nine parameters in it, one each for the parameters being passed to the stored procedure. The code sets the parameters values based on text boxes in a form, opens the connection, calls the **ExecuteNonQuery** method, and then closes the connection.

```
' Visual Basic
Dim cmdresults As Integer
' The following two property settings can also be done
' in the Properties window, but are shown here for completeness.
OleDbcommand2.CommandText = "NewAuthor"
OleDbCommand2.CommandType = CommandType.StoredProcedure

' Set parameter values. In this case, all parameter values
' are strings.
OleDbCommand2.Parameters("au_id").Value = TextBox1.Text
OleDbCommand2.Parameters("au_lname").Value = TextBox2.Text
OleDbCommand2.Parameters("au_fname").Value = TextBox3.Text
OleDbCommand2.Parameters("phone").Value = TextBox4.Text
OleDbCommand2.Parameters("address").Value = TextBox5.Text
OleDbCommand2.Parameters("city").Value = TextBox6.Text
OleDbCommand2.Parameters("st").Value = TextBox7.Text
OleDbCommand2.Parameters("zip").Value = TextBox8.Text
OleDbCommand2.Parameters("contract").Value = CheckBox1.Checked

OleDbConnection2.Open()
Try
   cmdresults = OleDbcommand2.ExecuteNonQuery()
Catch ex as Exception
   MessageBox.Show("Failed to execute command")
End Try
OleDbConnection2.Close()
MessageBox.Show("Number of records inserted = " & cmdresults.ToString)

// C#
int cmdresults = 0;
// The following two property settings can also be done
// in the Properties window, but are shown here for completeness.
OleDbCommand2.CommandText = "NewAuthor";
OleDbCommand2.CommandType = CommandType.StoredProcedure;

// Set parameter values. In this case, all parameter values
// are strings.
OleDbCommand2.Parameters["au_id"].Value = TextBox1.Text;
OleDbCommand2.Parameters["au_lname"].Value = TextBox2.Text;
OleDbCommand2.Parameters["au_fname"].Value = TextBox3.Text;
OleDbCommand2.Parameters["phone"].Value = TextBox4.Text;
OleDbCommand2.Parameters["address"].Value = TextBox5.Text;
OleDbCommand2.Parameters["city"].Value = TextBox6.Text;
```

```
OleDbCommand2.Parameters["st"].Value = TextBox7.Text;
OleDbCommand2.Parameters["zip"].Value = TextBox8.Text;
OleDbCommand2.Parameters["contract"].Value = CheckBox1.Checked;

OleDbConnection2.Open();
try
{
   cmdresults = OleDbCommand2.ExecuteNonQuery();
}
catch (Exception ex)
{
   MessageBox.Show("Failed to execute command");
}
OleDbConnection2.Close();
MessageBox.Show("Number of records inserted = " + cmdresults.ToString());
```

Introduction to DataCommand Objects in Visual Studio | Working with Data Commands: High-Level Process | Setting and Getting Data Command Parameters | Executing a Data Command that Returns a Result Set | Executing a Data Command that Returns a Single Value

Executing a Data Command that Returns a Single Value

At times, you might want to execute a database command or function that returns a single value — that is, a *scalar value*. Because you are returning only one value, this type of command is typically not performed with datasets. A typical example is an SQL statement that returns an aggregate value (SUM, COUNT, and so on). Other examples are a stored procedure that takes a credit card number and returns an authorization code, or a procedure that takes a product code and returns a product name.

> **Note** If you are using a dataset, you can aggregate values of data table columns using column expressions. For more information, see Creating Dataset Columns Using Expressions.

To execute a command that returns a scalar value

1. Add a data command to your form or component. For more information, see Adding Data Commands to a Form or Component.
2. Set the data command object's CommandText property to an SQL statement or the name of a stored procedure.
3. Set the **CommandType** property to **CommandType.Text** (for a statement) or **CommandType.StoredProcedure** (for a stored procedure). These values are defined in the CommandType enumeration.
4. If the command takes parameters, set them. For more information, see Setting and Getting Data Command Parameters.
5. Open the connection associated with the data command.
6. Call the command's ExecuteScalar method, setting the result to a variable of the appropriate data type.
7. Close the connection.

The following example shows how to use a data command to execute an SQL statement that returns a scalar value. The statement queries a products table. Its takes a product ID code passed as a parameter, and returns an integer value indicating the quantity in stock for that product. In this example, there is no aggregate function (for example, SUM), because the quantity in stock is stored as a column value in the Products table.

```
' Visual Basic
Dim scalarcmd As String
Dim qtyinstock As Integer
scalarcmd = "SELECT UnitsInStock FROM Products WHERE (ProductID = ?)"
OleDbCommand3.CommandType = CommandType.Text
OleDbCommand3.CommandText = scalarcmd
OleDbCommand3.Parameters("productid").Value = txtProductID.Text
OleDbConnection1.Open()
qtyinstock = CType(OleDbCommand3.ExecuteScalar(), Integer)
OleDbConnection1.Close()
MessageBox.Show("QtyinStock = " & qtyinstock.ToString)

// C#
string scalarcmd;
int qtyinstock;
scalarcmd = "SELECT UnitsInStock FROM Products WHERE (ProductID = ?)";
OleDbCommand3.CommandType = CommandType.Text;
OleDbCommand3.CommandText = scalarcmd;
OleDbCommand3.Parameters["productid"].Value = txtProductID.Text;
OleDbConnection1.Open();
qtyinstock = (int)(OleDbCommand3.ExecuteScalar());
OleDbConnection1.Close();
MessageBox.Show("QtyinStock = " + qtyinstock.ToString());
```

Dataset Updates in Visual Studio .NET

When you work with datasets — disconnected stores of records residing in memory — there are a number of issues associated with updating. When data is modified in a dataset, the dataset tracks those changes. You can then send dataset changes to other processes, such as the original data source or some other component. Throughout the update process there are several raised events where data validation, concurrency evaluation, and application logic can be applied.

> **Note** In Windows Forms, the data-binding architecture takes care of sending changes from data-bound controls to the dataset, and you do not have to explicitly update the dataset with your own code. For more information, see Windows Forms Data Architecture.

The topics in this section describe how dataset updates work and how to update, insert, and delete records in a dataset as well as the underlying data source.

> **Note** When you deploy an application that includes Visual Studio data-access components, you must make sure that the user installing the application has version 2.7 or later of the Microsoft Data Access Components (MDAC). For more information, see Adding a Launch Condition for Microsoft Data Access Components.

: Describes how to check that the correct version of the ADO.NET data access components is available when you install your application.

Introduction to Dataset Updates

Because a dataset is effectively a cache — an in-memory copy — of data, the process of writing information to the original data source is separate from the process of modifying the data in the dataset.

> **Note** In some instances, you might not be using a dataset at all. It is possible to send updates directly to a data source (generally a database) by calling an SQL statement or stored procedure and passing it update information. For more information about communicating directly with a data source, see Introduction to DataCommand Objects in Visual Studio.

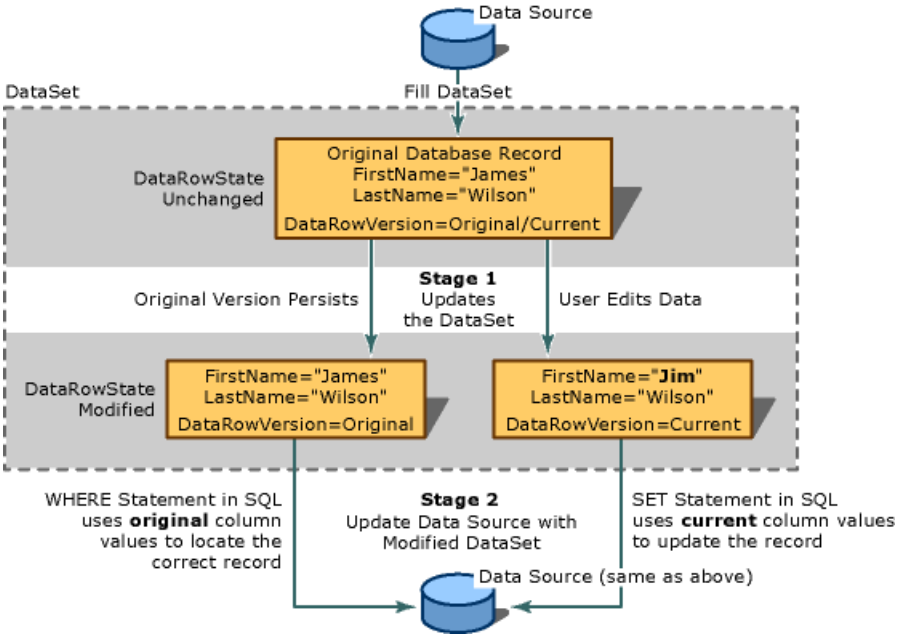
Two-Stage Updates

Updating a data source via a dataset is a two-step process. The first step is to update the dataset with new information — new records, changed records, or deleted records. If your application is concerned only with the dataset — for example, after updating the dataset, you send it to another application that will perform further processing of the dataset — then you are finished with the update.

> **Note** In Windows Forms, the data-binding architecture takes care of sending changes from data-bound controls to the dataset, and you do not have to explicitly update the dataset with your own code. For more information, see Windows Forms Data Architecture.

If you are updating a data source (such as a database), the second step is to send the changes from the dataset to the original data source. That is, the process of updating the dataset does not also write the changes through to an underlying data source; you must explicitly perform this second step. You typically accomplish this by calling the Update method of the same data adapter that you used to populate the dataset, although you can also use different adapters, for example, to move data from one data source to another or to update multiple data sources.

Two-stage update process and the role of the DataRowVersion in a successful update



For more information about transferring changes from the dataset to the database, see Database Updates from Datasets.

Structurally, a dataset makes data available as sets of collections. Datasets contain collections of tables. Tables contain collections of rows. Tables are exposed as a collection of the DataSet object and records are available in the Rows collection of DataTable objects. Making changes to data in a dataset by simply manipulating these collections using base collection methods is possible, but if you intend to update an underlying data source you must use the methods specifically designed for dataset modification.

For example, to remove a record from a data table, you could call the RemoveAt Method of the table's **Rows** collection, which physically deletes the record from the dataset. If you are using the dataset only as a structured store for data and are not concerned about transmitting change information to another application, manipulating collections this way is an acceptable way of updating a dataset.

However, if you intend to send changes to a data source or another application, you need to maintain change information (that is, metadata) about each update. Later, when you send changes to the data source or application, the process will have the information it needs to locate and update the proper records. For example, if you delete a record in the dataset, information about

the deleted record has to be maintained in the dataset so when the **DeleteCommand** of the data adapter is invoked there will be enough historic information to locate the original record in the data source so it can be deleted. For more information, see "Maintaining Information About Changes" below. For more information, see Updating, Inserting, and Deleting Records in a Dataset .

Merging Datasets

You can update the contents of a dataset by merging — that is, by copying the contents of one dataset (referred to as the *source* dataset) into the calling dataset (referred to as the *target* dataset). When you merge datasets, new records in the source dataset are added to the target dataset. Additionally, extra columns in the source dataset are added to the target dataset. Merging datasets is particularly useful when you have a local dataset and get a second dataset from another application or from a component such as an XML Web service, or just need to integrate data from multiple datasets.

When merging datasets, you can also pass an optional **Boolean** argument (*preserveChanges*) that tells the **Merge** method whether to retain existing modifications in the target dataset. Because datasets maintain multiple versions of records, it is important to keep in mind that more than one version of the records is being merged. The following table illustrates a record in two datasets that will be merged:

DataRowVersion	Target Dataset	Source Dataset
Original	James Wilson	James C. Wilson
Current	Jim Wilson	James C. Wilson

Calling the **Merge** method on the above table with `preserveChanges=false targetDataset.Merge(sourceDataset)` results in the following:

DataRowVersion	Target Dataset	Source Dataset
Original	James C. Wilson	James C. Wilson
Current	James C. Wilson	James C. Wilson

Calling the **Merge** method with `preserveChanges = true targetDataset.Merge(sourceDataset, true)` results in the following:

DataRowVersion	Target Dataset	Source Dataset
Original	James C. Wilson	James C. Wilson
Current	Jim Wilson	James C. Wilson

> **Caution** In the preserveChanges=**true** scenario, if the **RejectChanges** method is called on a record in the target dataset, it will revert to the original data from the source dataset. This means that if you went to update the original data source with the target dataset, it may not be able to find the original row to update. However, in the case of a concurrency violation (a situation where another user modified a record in the data source after the dataset was filled), filling another dataset with the updated records from the data source and then performing a merge will prevent a concurrency violation. For more information, see Concurrency Control in ADO.NET and Merging Datasets.

Update Constraints

To make changes to an existing data row, you add or update data in the individual columns. If the dataset contains constraints (such as foreign keys, or nonnullable constraints), it is possible that as you update a record — after you've finished updating one column but before you get to the next one — the record can temporarily be in an error state.

To prevent premature constraint violations you can temporarily suspend update constraints. This serves two purposes:

- It prevents an error from being thrown when you update one column before you get to another column.
- It suspends certain update events from being raised (events that are often used for validation).

After you have completed an update, you can re-enable constraint checking, which also re-enables update events and raises them.

> **Note** In Windows Forms, the data-binding architecture built into the datagrid suspends constraint checking until focus moves out of a row, and you do not have to explicitly call the **BeginEdit**, **EndEdit** or **CancelEdit** methods.

Constraints are automatically disabled when the **Merge** method is invoked on a dataset. When the merge is complete if there are any constraints on the dataset that cannot be enabled a **ConstraintException** is thrown. In this situation, the **EnforceConstraints** property is set to **false** and all constraint violations must be resolved before resetting the **EnforceConstraints** property to **true**.

After you have completed an update, you can re-enable constraint checking, which also re-enables update events and raises them.

For more information about suspending events, see Suspending Update Constraints. For more information about events, see

Data Update Events.

Dataset Update Errors

When you update a record in a dataset, there is the possibility of an error. For example, you might inadvertently write data to a column that is of the wrong data type, or too long, or that has some other integrity problem. In addition, you may have application-specific validation checks that can raise custom errors during any stage of an update event. For more information, see Data Validation in Datasets.

Maintaining Information About Changes

Information about the changes in a dataset is maintained in two ways: by flagging the row that indicates whether it has been changed (**RowState**), and by keeping multiple copies of a record (**DataRowVersion**). By using this information, processes can determine what has changed in the dataset and can send appropriate updates to the data source.

RowState Property

The RowState property of a **DataRow** object is a value that provides information about the status of a particular row of data.

The following table details the possible values of the DataRowState enumeration:

DataRowState Value	Description
Added	The row has been added as an item to a DataRowCollection. (A row in this state does not have a corresponding original version since it did not exist at the time the last **AcceptChanges** method was called).
Deleted	The row was deleted using the DataRow.Delete Method of a DataRow object.
Detached	The row has been created but is not part of any **DataRowCollection**. A **DataRow** object is in this state immediately after it has been created and before it is added to a collection, or if it has been removed from a collection.
Modified	A column value in the row has been changed in some way.
Unchanged	The row has not changed since **AcceptChanges** was last called.

DataRowVersion Enumeration

Datasets maintain multiple versions of records. The DataRowVersion enumeration of a **DataRow** object is a value that can be used to return a specific version of a **DataRow** object.

The following table details the possible values of the **DataRowVersion** enumeration:

DataRowVersion Value	Description
Current	The current version of a record contains all modifications performed on the record since the last time **AcceptChanges** has been called. If the row has been deleted there is no current version.
Default	The default value of a record, as defined by the dataset schema or data source.
Original	The original version of a record is a copy of the record as it was the last time changes were committed in the dataset. In practical terms, this is typically the version of a record as read from a data source.
Proposed	The proposed version of a record that is available temporarily, while you are in the middle of an update — that is, between the time you called the **BeginEdit** method and the **EndEdit** method. You typically access the proposed version of a record in a handler for an event such as **RowChanging**. Invoking the **CancelEdit** method reverses the changes and deletes the proposed version of the data row.

The original and current versions are useful when update information is transmitted to a data source. Typically, when an update is sent to the data source, the new information for the database is in the current version of a record, and information from the original version is used to locate the record to update. For example, in a case where the primary key of a record is changed, you must have a way to locate the proper record in the data source, in order to update the changes. If no original version existed, the record would most likely be appended to the data source resulting not only in an extra unwanted record, but in one record that is inaccurate and out of date. The two versions are also used in concurrency control; you can compare the original version against a record in the data source to determine if the record has changed since it was loaded into the dataset. For more information, see Concurrency Control in ADO.NET.

The proposed version is useful when you need to perform validation before actually committing the changes to the dataset.

Even if records have changed, there are not always original or current versions of that row. When you insert a new row into the table, there is no original version, only a current version. Similarly, if you delete a row by calling the table's **Delete** method, there is an original version, but no current version.

You can test to see if a specific version of a record exists by querying a data row's HasVersion property. You can access either version of a record by passing a DataRowVersion enumeration value as an optional argument when you request the value of a column.

Getting Changed Records

It is common that you do not update every record in a dataset. For example, a user might be working with a Windows Forms DataGrid control that displays many records. However, the user might update only a few records, delete one, and insert a new one. Datasets and data tables provide a method (**GetChanges**) for returning only the rows that have been modified.

You can create subsets of changed records using the **GetChanges** method of either the data table (DataTable.GetChanges) or of the dataset (DataSet.GetChanges) itself. If you call the method for the data table, it returns a copy of the table with only the changed records. Similarly, if you call the method on the dataset, you get a new dataset with only changed records in it. **GetChanges** by itself will return all changed records, whereas by passing the desired **DataRowState** as a parameter to the **GetChanges** method you can specify what subset of changed records you want: newly added records, records marked for deletion, detached records, and modified records.

Getting a subset of changed records is particularly useful when you want to send records to another component for processing. Instead of sending the entire dataset, you can reduce the overhead of communicating with the other component by getting only the records that the component needs. For more information, see Retrieving Changed Rows.

Committing Changes in the Dataset

As changes are made in the dataset, the **RowState** property of changed rows is set. The original and current versions of records are established and maintained and made available to you via the **RowVersion** property. The metadata stored in these properties representing the changes is needed to send the proper updates to the data source.

If the changes reflect the current state of the data source, you no longer need to maintain this information. Typically, there are two times when the dataset and its source are in synch:

- Immediately after you have loaded information into the dataset, such as when you read data from the source.
- After sending changes from the dataset to the data source, (but not before, because you would lose the change information required to send changes to the database).

You can commit the pending changes to the dataset by calling the **AcceptChanges** method. Typically, **AcceptChanges** would be called at the following times in your application.

- After you have loaded the dataset. If you load a dataset by calling a data adapter's **Fill** method, the data adapter automatically commits changes for you. However, if you load a dataset by merging another dataset into it, you have to commit the changes manually.

  > **Note** You can prevent the data adapter from automatically committing the changes when calling the **Fill** method by setting the **AcceptChangesDuringFill** property of the adapter to false. If set to false, the **RowState** of each row inserted during the fill is set to **Added**.

- After you have sent dataset changes to another process, such as an XML Web service.

  > **Caution** Committing the change this way erases any change information. Do not commit changes until after you have performed any operations in which your application depends on knowing what changes have been made in the dataset.

This method accomplishes the following:

- Writes the **Current** version of a record into its **Original** version, overwriting the original version.
- Removes any row whose **RowState** property is set to **Deleted**.
- Sets the **RowState** property of a record to **Unchanged**.

The **AcceptChanges** method is available at three levels. You can call it on a **DataRow** object, which commits changes for just that row. You can also call it on a **DataTable** object to commit all rows in a table, or on the **DataSet** object to commit all pending changes in all records of all tables of the dataset.

The following table describes which changes are committed based on what object the method is called on.

Method	Result
DataRow.AcceptChanges	Changes are committed only on the specific row
DataTable.AcceptChanges	Changes are committed on all rows in the specific table
DataSet.AcceptChanges	Changes are committed on all rows in all tables of the dataset

> **Note** If you load a dataset by calling a data adapter's **Fill** method, you do not have to explicitly accept changes; by default the **Fill** method calls the **AcceptChanges** method when it has finished populating the data table.

A related method, **RejectChanges**, undoes the effect of changes by copying the **Original** version back into the **Current** version of records and setting the **RowState** of each record back to **Unchanged**.

Data Validation

In order to verify that the data in your application meets the requirements of the processes that it is passed to, you often have to add validation. This might involve checking that a user's entry into a form is correct, validating data sent to your application by another application, or even checking that information calculated within your component falls within the constraints of your data source and application requirements.

You can validate data in several ways:

- In the presentation layer, by adding validation to forms. If you are working with Web Forms pages, you can use validation controls for this purpose. For more information, see Introduction to Validating User Input in Web Forms. If you are working with Windows Forms, you typically associate validation with TextBox or RichTextBox controls. Another way to control valid input from a user on a Windows Form is the Masked Edit Control.
- In the data back end, by sending data to the data source — for example, the database — and allowing it to accept or reject the data. If you are working with a database that has sophisticated facilities for validating data and providing error information, this can be a practical approach because you can validate the data no matter where it comes from. However, it might not accommodate application-specific validation requirements. Additionally, having the data source validate data can result in numerous round trips to the data source depending on how your application facilitates resolving validation errors raised by the back end.

  > **Security Note** When using data commands with a CommandType property set to **Text**, carefully check information that is sent from a client before passing it to your database. Malicious users might try to send (inject) modified or additional SQL statements in an effort to gain unauthorized access or damage the database. Before you transfer user input to a database, you should always verify that the information is valid; it is a best practice to always use parameterized queries or stored procedures when possible. For more information, see Scripting Exploits.

- In the business layer, by adding code to your application to validate data. A good place to perform this type of validation is in the dataset. The dataset provides some of the advantages of back-end validation — such as the ability to validate changes to the data no matter how they were made — with the ability to provide application-specific validation. For more information, see Data Validation in Datasets.

Updating, Inserting, and Deleting Records in a Dataset

After your dataset is populated with data, you will typically perform some kind of manipulation of the data before sending it back to the data source or to another process or application. Since each record in a dataset is represented by a DataRow object, changes to a dataset are accomplished by updating and deleting individual rows. Additionally, new records can be inserted into the dataset by adding new **DataRow** objects to the **DataTable** objects' Rows collection.

You can manipulate the collection directly to delete records. However, if you want to send changes to the database or to another process, the dataset has to maintain change information for deleted rows. Data tables therefore provide special methods for deleting records so this information can be retained.

> **Note** In Windows Forms, the data-binding architecture takes care of sending changes from data-bound controls to the dataset, and you do not have to explicitly update the dataset with your own code. For more information, see Windows Forms Data Architecture.

If the dataset includes constraints, you can temporarily turn constraints off before making any updates, and then turn them back on afterward. For more information, see Suspending Update Constraints.

Updating Existing Records in a Dataset

In order to edit an existing record in a dataset, you need to access a particular column of data in a particular row. The data in both typed and untyped datasets can be accessed via the following:

- With the indices of the tables, rows, and columns collections.
- By passing the table and column names as strings to their respective collections.

Although typed datasets can use the same syntax as untyped datasets, there are additional advantages to using typed datasets. For more information, see the "To update existing records using typed datasets" section below.

To update existing records in either typed or untyped datasets

- Assign a value to a specific column within a DataRow object.

  The table and column names of untyped datasets are not available at design time and must be accessed through their respective indices.

  The following example shows how to update the data in the first two columns of the fifth record of the first table in `dataset1`, accessing the data values with the tables, rows, and items (columns) collection indices:

  ```
  ' Visual Basic
  dataset1.Tables(0).Rows(4).Item(0) = "Wingtip Toys"
  dataset1.Tables(0).Rows(4).Item(1) = "Buffalo"

  // C#
  dataset1.Tables[0].Rows[4].ItemArray[0] = "Wingtip Toys";
  dataset1.Tables[0].Rows[4].ItemArray[1] = "Buffalo";
  ```

  The following example shows how to update the same data as the preceding example, replacing the collection indices with table, and column names passed as strings:

  ```
  ' Visual Basic
  dataset1.Tables("Customers").Rows(4).Item("CompanyName") = "Wingtip Toys"
  dataset1.Tables("Customers").Rows(4).Item("City") = "Buffalo"

  // C#
  dataset1.Tables["Customers"].Rows[4]["CompanyName"] = "Wingtip Toys";
  dataset1.Tables["Customers"].Rows[4]["City"] = "Buffalo";
  ```

To update existing records using typed datasets

- Assign a value to the specific column within a **DataRow** object.

  Typed datasets utilize early binding, which exposes the table and column names as properties at design time. This results in code that is both easier to read and write.

  The following example shows how to update the data in the `CompanyName` and `City` columns of the fifth record in the `Customers` table in the `DsCustomers1` dataset:

  ```
  ' Visual Basic
  DsCustomers1.Customers(4).CompanyName = "Wingtip Toys"
  DsCustomers1.Customers(4).City = "Buffalo"

  // C#
  dsCustomers1.Customers[4].CompanyName = "Wingtip Toys";
  dsCustomers1.Customers[4].City = "Buffalo";
  ```

Inserting New Records into a Dataset

In order to add new records into a dataset, a new data row must be created and added to the DataRow collection of a data table. The following procedure details how to insert additional rows into a DataTable object in a dataset. For this example, it is assumed the `ExistingTable` is in a dataset and has two columns named `FirstName` and `LastName`.

To add new records to a typed or untyped dataset

1. Call a data table's NewRow method to create a new, blank record.

   This new record inherits its column structure from the data table's DataColumnCollection.

   ```
   ' Visual Basic
   Dim anyRow as DataRow = ExistingTable.NewRow

   // C#
   DataRow anyRow = ExistingTable.NewRow();
   ```

2. Update the new row as if it were an existing record.

   ```
   ' Visual Basic
   anyRow(0) = "Jay"
   anyRow(1) = "Stevens"
   ' or
   anyRow("FirstName") = "Jay"
   anyRow("LastName") = "Stevens"

   // C#
   anyRow[0] = "Jay";
   anyRow[1] = "Stevens";
   // or
   anyRow["FirstName"] = "Jay";
   anyRow["LastName"] = "Stevens";
   ```

3. Add the new record to the table by calling the Add method of the **DataRowCollection** object.

   ```
   ' Visual Basic
   ExistingTable.Rows.Add(anyRow)

   // C#
   ExistingTable.Rows.Add(anyRow);
   ```

Inserting New Records with Typed Datasets

Typed datasets expose the column names as properties of the **DataRow** object.

To add new records using typed datasets

- The following example illustrates the same three steps above, except this time the code is modified for use with a typed dataset:

   ```
   ' Visual Basic
   Dim anyRow as DataRow = DatasetName.ExistingTable.NewRow
   anyRow.FirstName = "Jay"
   anyRow.LastName = "Stevens"
   ExistingTable.Rows.Add(anyRow)

   // C#
   DataRow anyRow = DatasetName.ExistingTable.NewRow();
   anyRow.FirstName = "Jay";
   ```

```
anyRow.LastName = "Stevens";
ExistingTable.Rows.Add(anyRow);
```

Deleting Records in a Dataset

In order to retain the information that the dataset needs to properly update the data source, use the **Delete** method to remove rows in a data table. If your application does not need to send updates back to a data source then it is possible to remove records by directly accesing the data row collection.

To delete records from a data table

- Call the data row's Delete method.

  This method does not physically remove the record; instead, it marks the record for deletion.

  > **Note** If you get the count property of a **DataRowCollection**, the resulting count includes records that have been marked for deletion. To get an accurate count of only records that are not marked for deletion, you can loop through the collection looking at the RowState property of each record. Alternatively, you can create a data view of a dataset that filters based on row state and get the count property from there.

  The following example shows how to call the **Delete** method to mark the first row in the Customers table as deleted:

```
' Visual Basic
DsCustomers1.Customers.Rows(0).Delete()

// C#
dsCustomers1.Customers.Rows[0].Delete();
```

Suspending Update Constraints

If a dataset contains constraints (such as a foreign-key constraint), updating a column in a record can violate the constraint: After you have finished updating one column but before you get to the next one, the record can temporarily be in an error state. For example, imagine that you have a data table in your dataset with two columns that do not allow null values. As soon as you start to write a new record there will always be a null value in at least one of the columns (you can only write one column at a time). If there were no mechanism to allow temporary constraint suspension, an error would be raised every time after writing the first column and before writing the second.

To suspend update constraints

1. Before changing data in a data row, call the **DataRow** object's BeginEdit method.

   Note Changes you make to the row after calling **BeginEdit** are saved.

2. Make the updates to that row.
3. Call the EndEdit method to commit changes to the row and re-enable constraint checking.

   The RowChanging event is raised.

4. Call the row's CancelEdit method to discard changes to the row.

   The following example shows a simple update that is bracketed with **BeginEdit** and **EndEdit** method calls. This example assumes that you have a table called `Customers` in a typed dataset called `DsCustomers1`.

```
' Visual Basic
DsCustomers1.Customers(4).BeginEdit()
DsCustomers1.Customers(4).CompanyName = "Wingtip Toys"
DsCustomers1.Customers(4).City = "Buffalo"
DsCustomers1.Customers(4).EndEdit()

// C#
dsCustomers1.Customers[4].BeginEdit();
dsCustomers1.Customers[4].CompanyName = "Wingtip Toys";
dsCustomers1.Customers[4].City = "Buffalo";
dsCustomers1.Customers[4].EndEdit();
```

Merging Datasets

You can merge the contents of one dataset (referred to as the *source* dataset) into another dataset (referred to as the *target* dataset). Some typical examples of when you would perform a merge are:

- You have a main dataset containing your working data, and you get a second dataset containing updates or records to be added to it. This is a typical scenario when you are working with an XML Web service that returns a dataset to you as the result of a method call.
- Your application gets a dataset from two different components but needs to work with the data in a single dataset. For example, you might get company information from one component and stock price information from another.

To copy information from one dataset to another, you use a dataset's Merge method. You can specify merge options to achieve a variety of goals:

- Add new records to one dataset by copying them from another dataset.
- Update the state of records in one dataset based on another. In this situation, the second dataset contains information not only about new records, but also changed records and deleted records, and you want your first dataset to reflect all these changes.
- Copy not only new records and changes, but specify what to do if the datasets do not have the same schemas.

To merge one dataset into another

- Call the Merge method of the target dataset, passing it the source dataset containing the records to be merged.

  The following example shows how to merge two datasets with the default setting of **PreserveChanges** = **false**:

  ```
  ' Visual Basic
  targetDataset.Merge(sourceDataset)

  // C#
  targetDataset.Merge(sourceDataset);
  ```

  The following example shows how to merge two datasets with the **PreserveChanges** argument set to **true**:

  ```
  ' Visual Basic
  targetDataset.Merge(sourceDataset, True)

  // C#
  targetDataset.Merge(sourceDataset, true);
  ```

Committing Changes in a Dataset

As you make changes to records in a dataset by updating, inserting, and deleting records, the dataset maintains original and current versions of the records. In addition, each row's **RowState** property is set to indicate whether the records are in their original state or if they have been updated, inserted, or deleted. This information is useful when you need to find a particular version of a row. Typically, you would get a subset of all changed records to send to another process. For more information, see Retrieving Changed Rows. After you have processed all the changed rows, you can commit the changes by calling the **AcceptChanges** method of the dataset.

To commit changes in a dataset

- Call the dataset's AcceptChanges method.

  The following example shows how to call the **AcceptChanges** method to commit changes in the `Customers` table after updating a data source:

```
' Visual Basic
OleDbDataAdapter1.Update(Dataset1, "Customers")
Dataset1.Customers.AcceptChanges()

// C#
OleDbDataAdapter1.Update(Dataset1, "Customers");
Dataset1.Customers.AcceptChanges();
```

Copying Information from Another Dataset Before Committing Changes

To copy information from another dataset and then commit the changes

1. Call the dataset's Merge method.
2. Call the dataset's AcceptChanges method.

   The following example shows how to commit changes in a dataset after using the **Merge** method to copy information from a second dataset:

```
' Visual Basic
Dataset1.Merge(Dataset2)
Dataset1.AcceptChanges()

// C#
Dataset1.Merge(Dataset2);
Dataset1.AcceptChanges();
```

Identifying and Returning Changed Rows

Datasets maintain multiple versions of data rows in order to locate the original records in a data source. Before performing an update to the data source, you may want to examine specific rows. The topics in this section provide details on determining if records have changed, as well as retrieving particular versions of records .

In This Section

Checking for Changed Rows
Explains how to determine whether dataset records have changed and how to determine whether a record is new, changed, or deleted.
Retrieving Changed Rows
Describes how to extract only changed records from a dataset.
Locating an Individual Row in a Dataset
Describes how to find a specific data row by searching for a primary key value.
Getting Specific Versions of a Row
Describes how to return a record by passing a **DataRowVersion** enumeration value.
Locating Rows that Have Errors
Describes how to determine if errors exist in a dataset and the method used to find rows that have errors.

Checking for Changed Rows

When changes are made to records in a dataset, information about those changes is stored until you commit them (calling the **AcceptChanges** method of a dataset, data table, or data row commits the changes).

Changes are tracked in each data row two ways:

- Each record retains the type of change that has been made to it through the **DataRow** object's **RowState** property.
- The dataset maintains multiple copies of changed rows — the original (before changes) and current (after changes) version — that you can access. During the short period when a change is pending (during the time that you can respond to the **RowChanging** event), a third version — the proposed version — is available as well. For more information, see Introduction to Dataset Updates.

Determining If There Are Changed Rows

The **HasChanges** method of a dataset returns **true** if changes have been made in the dataset.

To determine if any changes have been made to any rows

- Call the HasChanges method of a dataset to check for changed rows.

  The following example shows how to check the return value from the **HasChanges** method to detect whether there are any changed rows in a dataset named `myDataset`.

```
' Visual Basic
If myDataset.HasChanges() Then
     ' Changed rows were detected, add appropriate code.
Else
     ' NO changed rows were detected, add appropriate code.
End If

// C#
if (myDataSet.HasChanges())
{
   // Changed rows were detected, add appropriate code.
}
else
{
   // NO changed rows were detected, add appropriate code.
}
```

Determining the Type of Changes

You can also check to see what type of changes have been made in a dataset by passing a value from the DataRowState Enumeration to the **HasChanges** method.

To determine what type of changes have been made to a row

- Pass a **DataRowState** value to the **HasChanges** method.

The following example shows how to check a dataset named `myDataset` to determine if there have been any new rows added to it:

```
' Visual Basic
If myDataset.HasChanges(DataRowState.Added) Then
   ' New rows have been added to the dataset, add appropriate code.
Else
   ' No new rows have been added to the dataset, add appropriate code.
End If

// C#
if (myDataSet.HasChanges(DataRowState.Added))
{
```

```
    // Changed rows were detected, add appropriate code.
}
else
{
    // NO changed rows were detected, add appropriate code.
}
```

Introduction to Dataset Updates | DataSet.HasChanges Method | DataRowState Enumeration |
Code: Locating Changed Data in a DataSet (Visual Basic)

Retrieving Changed Rows

You often want to extract from a dataset only the records that have been changed. This is often true, for example, when your application has processed some records in a dataset and needs to send only the changed records back to the data source or to another process.

> **Note** After you commit changes to a dataset or data table (by calling the **AcceptChanges** method), all rows are set to unchanged and the information needed by the **GetChanges** method no longer exists. If your application needs to process changed rows, you must do so before calling the **AcceptChanges** method.

Calling the GetChanges method of a dataset or data table returns a new dataset or data table that contains only records that have been changed. If you want to get only specific records — for example, only new records or only changed records — you can pass as a parameter a row state value defined using the DataRowState enumeration.

To get all changed records from a dataset or data table

- Call the GetChanges method of a dataset or data table.

  The following example creates a new dataset called `myChangedRecords` and populates it with all the changed records from another dataset called `myDataSet`.

```
' Visual Basic
Dim myChangedRecords as DataSet
myChangedRecords = myDataSet.GetChanges()

// C#
DataSet myChangedRecords = myDataSet.GetChanges();
```

To get changed records that are of a specific RowState

- Call the **GetChanges** method of a dataset or data table and pass a **DataRowState** value as an argument.

  The following example shows how to create a new dataset called `myChangedRecords` and populate it with only records that have been added to the `myDataSet` dataset.

```
' Visual Basic
Dim myChangedRecords as DataSet
myChangedRecords = myDataSet.GetChanges(DataRowState.Added)

// C#
DataSet myChangedRecords = myDataSet.GetChanges(DataRowState.Added);
```

See Also

Dataset Updates in Visual Studio .NET | DataSet.GetChanges Method | DataRowState Enumeration | DataRowVersion Enumeration | Code: Locating Changed Data in a DataSet (Visual Basic)

Locating an Individual Row in a Dataset

Most applications that consume data need to access specific records that satisfy some kind of criteria. In order to find a particular row in a dataset you invoke the Find Method of the **DataRowCollection**. If the primary key exists, a **DataRow** object is returned. If the primary key cannot be found, a null value is returned.

To find a specific row within a dataset

- Call the **Find** method of the **Rows** collection passing the primary key as an argument.

  The following example shows how to declare a new row (`rowFoundRow`) and assign it the return value of the **Find** method. If the primary key is found the contents of column index one are displayed in a message box.

```
' Visual Basic
Dim n As String = "primaryKeyValue to be found"
Dim rowFoundRow as DataRow = anyTable.Rows.Find(n)
If Not (rowFoundRow Is Nothing) Then
   MessageBox.Show(CType(rowFoundRow(1), String))
Else
   MessageBox.Show("A row with the primary key of " & _
      n & " could not be found")
End If

// C #
string n = "primaryKeyValue to be found";
DataRow rowFoundRow = anyTable.Rows.Find(n);
if (rowFoundRow != null)
{
   MessageBox.Show((string)rowFoundRow[1]);
}
else
{
MessageBox.Show("A row with the primary key of " +
   n + " could not be found");
}
```

Updating, Inserting, and Deleting Records in a Dataset | DataRowCollection.Find Method | DataTable.Select Method | Code: Locating Changed Data in a DataSet (Visual Basic)

Getting Specific Versions of a Row

Particular versions of records are available before changes are committed to that data row. For example, before calling the **AcceptChanges** method, your application can access the different versions of a record (as defined in the **DataRowVersion** enumeration) and process the changes accordingly.

> **Note** Different versions of a row exist only after a row has been edited, and before the row has had the **AcceptChanges** method called. After the **AcceptChanges** method has been called, the current and original versions are the same.

Passing the **DataRowVersion** value along with the column index (or column name as a string) returns the value from that column's particular row version. The changed column is identified during the **ColumnChanging** and **ColumnChanged** events, so that is a good time to inspect the differing row versions for validation purposes. However, if you have temporarily suspended constraints, those events will not be raised and you will need to programmatically identify which columns have changed. You can do this by iterating through the **Columns** collection and comparing the different **DataRowVersion** values.

To get a specific version of a record

- Access the value of a column and add a parameter to the index indicating which version of a row you want to return. Possible values for the row version are defined in the DataRowVersion enumeration.

  The following example shows how you can use a **DataRowVersion** value to get the original value of the `CompanyName` field:

```
' Visual Basic
Dim sOrigCompName As String
sOrigCompName = CType(DsCustomers1.Customers(0)("CompanyName", _
DataRowVersion.Original), String)

// C#
string origCompName;
origCompName = (string)
(dsCustomers.Customers[0]["CompanyName", DataRowVersion.Original]);
```

Locating Rows that Have Errors

If your application does not use the **RowUpdated** or **ColumnUpdated** event handlers to catch errors during the update process, you will need to find the error programmatically.

To locate a row that has errors as a result of an update attempt

1. Set the **HasErrors** property to locate in the dataset the row that has errors.
2. If you do not find the error in the dataset, iterate through the collections of tables, then the rows to find the row with the error.

```
' Visual Basic
Private Sub finderr2()
        Dim dt As DataTable
        Dim dr As DataRow
        For Each dt In anyDataset.Tables
            For Each dr In dt.Rows
                If dr.HasErrors Then
                    ' Row found! Add code to reconcile error.
                    dr.ClearErrors() ' Clear the error.
                    ' Re-attempt the update.
                End If
            Next
        Next
    End Sub

// C#
private void Find_Errors2()
{
   DataSet anyDataset = null;
   foreach (DataTable dt in anyDataset.Tables)
   {
      foreach (DataRow dr in dt.Rows)
      {
         if (dr.HasErrors)
         {
            // Row found! Add code to reconcile error.
            dr.ClearErrors();
            // Re-attempt the update.
         }
      }
   }
}
```

Validating Data

Datasets provide specific events that are raised as values in data rows change. Event handlers can be created to validate these changes based on your particular application requirements. The following topics detail these events and provide an explanation of the information passed to each event.

In This Section

Data Validation in Datasets
Provides an overview of events that can be used to analyze data before being committed to the dataset.
Validating Data During Column Changes
Describes the information returned during the **ColumnChanging** event.
Validating Data During Row Changes
Describes the information returned during the **RowChanging** event.

DataTable.ColumnChanging Event
Provides syntax and other reference information.
DataTable.RowChanging Event
Provides syntax and other reference information.

Data Validation in Datasets

You can confirm that data being written to a dataset is valid by building validation checks into the dataset itself. The dataset can check the data no matter how the update is being performed — whether directly by controls in a form, within a component, or in some other way. Because the dataset is part of your application, it is a logical place to build application-specific validation (unlike building the same checks into the database backend). Validation within a dataset can be accomplished:

- By creating keys, unique constraints, and so on as part of the actual schema definition of the dataset. For more information on incorporating validation into the schema definition, see Creating Primary and Unique Keys in XML Schemas.
- By creating your own application-specific validation that can check data during column and row changing events.
- By setting the DataColumn object's properties, such as **MaxLength**, **AllowDBNull**, and **Unique**.

There are several events that are raised by the **DataTable** object when a change is occurring in a record:

- The ColumnChanging and ColumnChanged events are raised during and after each change to an individual column. The **ColumnChanging** event is useful when you want to validate changes in specific columns. Information about the proposed change is passed as an argument with the event. For more information see Validating Data During Column Changes.
- The RowChanging and RowChanged events are raised during and after any change in a row. The **RowChanging** event is more general, in that it simply indicates that a change is occurring somewhere in the row; you do not know which column has changed. For more information see Validating Data During Row Changes.

By default, each change to a column therefore raises four events: first the **ColumnChanging** and **ColumnChanged** events for the specific column being changed, and then the **RowChanging** and **RowChanged** event. If multiple changes are being made to the row, the events will be raised for each change.

> **Note** The data row's **BeginEdit** method turns off the **RowChanging** and **RowChanged** events after each individual column change. In that case, the event is not raised until the **EndEdit** method has been called, when the **RowChanging** and **RowChanged** events are raised just once. For more information, see Suspending Update Constraints.

The event you choose depends on how granular you want the validation to be. If it is important that you catch an error immediately when a column is changed, build validation using the **ColumnChanging** event. Otherwise, use the **RowChanging** event, which might result in catching several errors at once. Additionally, if your data is structured in such a way that the value of one column is validated based on the contents of another column then you should perform your validation during the **RowChanging** event.

Validating Data During Column Changes

You can validate data when the column changes by responding to the **ColumnChanging** event. This event passes an event argument object with properties that give you access to the column being changed. Validation can also be performed during the **RowChanging** event, For more information see Validating Data During Row Changes.

To validate when a column changes

1. Create an event handler for the ColumnChanging event of a data table. For more information, see Writing Event Handlers (Visual Basic) or Events Tutorial (C#).
2. In the event handler, you can return the proposed and original values by examining the **ProposedValue** and **Row** properties:

```
' Visual Basic
Dim newValue As String = CType(e.ProposedValue, String)
Dim origvalue As String = CType(e.Row(e.Column), String)

// C#
string newValue = (string)e.ProposedValue;
string origValue = (string)(e.Row[e.Column]);
```

3. To get information about the column that is changing, examine the **Column** property that is passed to the handler:

```
' Visual Basic
Dim colDataType As String = e.Column.DataType.ToString()
Dim colName As String = e.Column.ColumnName

// C#
string colDataType = e.Column.DataType.ToString();
string colName = e.Column.ColumnName;
```

4. To reject the change, throw an exception.

```
' Visual Basic
' Throw the exception within the ColumnChanging event handler –
' in this case we will validate for a value that is < 10.

Private Sub dt_ColumnChanging(ByVal sender As Object, ByVal e As System.Data.DataColumnCh
angeEventArgs) Handles dt.ColumnChanging
   Dim newvalue As Integer = CType(e.ProposedValue, Integer)
   If newvalue < 10 Then
      MessageBox.Show(newvalue.ToString() & " is not less than 10")
      Throw New Exception(newvalue.ToString() & " is not less than 10")
   End If
End Sub
// C#
private void dt_ColumnChanging(object sender, System.Data.DataColumnChangeEventArgs e)
{
   int newvalue = (int)(e.ProposedValue);
   if (newvalue < 10)
   {
      MessageBox.Show(newvalue.ToString() + " is not less than 10");
      throw new Exception(newvalue.ToString() +
         " is not less than 10");
   }
}
```

Validating Data During Row Changes

You can validate data when the row changes by responding to the **RowChanging** event. Typed dataset classes expose a table-specific **RowChanging** event. For example, if the typed dataset contains a table called Employees, the **Employees** data table object raises a **EmployeesRowChanging** event. This event passes an event argument object that includes strongly typed properties to give you access to the column being changed. Validation can also be performed during the **ColumnChanging** event, For more information see Validating Data During Column Changes.

To validate when a row changes

1. Create an event handler for the RowChanging event of a data table. For more information see Writing Event Handlers (Visual Basic) or Events Tutorial (C#).

   If you are working with a typed dataset, you can respond to the table-specific event, such as **EmployeesRowChanging** or you can respond to the standard **RowChanging** event. However, both events are raised so performing the same validation in each event is unnecessary.

2. In the event handler, get changes to the row by extracting individual columns from the **Proposed** version of rows using syntax such as the following:

```
' Visual Basic
newFName = CType(e.Row("FirstName", DataRowVersion.Proposed), String)
// C#
newFName = (string)(e.Row["FirstName", DataRowVersion.Proposed]);
```

   Note If you are working with the table-specific event, the proposed versions of the columns are available as typed properties of the row, and you can access them using syntax such as the following:
   newFName = e.Row.FirstName
   .

3. Get the existing versions of columns using syntax such as the following:

```
' Visual Basic
oldFName = CType(e.Row("FirstName", DataRowVersion.Original), String)
// C#
oldFName = (string)(e.Row["FirstName", DataRowVersion.Original]);
```

4. Perform the validation. To reject the change, throw an exception. To accept the change, you do not need to perform any special logic.

   The following example shows how you can validate data in a row-changing event. The code checks that if a value already exists for the column `SecurityCode`, the new value cannot be null — that is, it prevents the column value from being deleted. In the event handler, the code makes sure that there is an existing value by using the data row's **HasVersion** property.

```
' Visual Basic
Private Sub employeetable_EmployeesRowChanging(ByVal sender As _
System.Object, ByVal e As dsEmployees.EmployeesRowChangeEvent) _
Handles employeetable.EmployeesRowChanging
   Dim original As String = ""
   Dim proposed As String = ""
   If e.Row.HasVersion(DataRowVersion.Original) Then
      original = _
         CType(e.Row("SecurityCode", DataRowVersion.Original), String)
   Else
      original = ""
   End If
   proposed = e.Row.SecurityCode

   If original <> "" Then
```

```
      If proposed = "" Then
         Throw (New Exception("Security Code cannot be blank"))
      End If
   End If
End Sub

// C#
private void employeetable_EmployeesRowChanging(object sender, dsEmployees.EmployeesRowCh
angeEvent e)
{
   string original = "";
   string proposed = "";
   if (e.Row.HasVersion(DataRowVersion.Original))
   {
      original =
      (string)(e.Row["SecurityCode", DataRowVersion.Original]);
   }
   else
   {
      original = "";
   }

   proposed = e.Row.SecurityCode;
   if (original != "")
   {
      if (proposed == "")
      {
         throw (new System.Exception("Security Code cannot be blank"));
      }
   }
}
```

Writing Dataset Changes to a Data Source

After the contents of a dataset are modified and validated, most applications will typically need to write the changes through to an underlying database. For more information about modifying datasets, see Updating, Inserting, and Deleting Records in a Dataset. For more information about validating datasets, see Validating Data.

The topics in this section describe some important dataset fundamentals regarding data source updating, as well as details on performing an update and handling potential errors.

In This Section

Database Updates from Datasets
Provides an overview of how to move dataset changes to a database.
Updating a Data Source with a Dataset
Describes the process of writing changes to a data source.
Responding to Database Update Errors
Describes how to determine if errors occur while writing changes to a dataset.

Manipulating Data Example Topics
Presents a series of specific example code topics for common tasks in working with data within your application using Visual Basic .NET.

Updating a Data Source with a Dataset

After your dataset has been modified and validated, it is likely that your application will want to send the new data back to a data source. In order to update a data source with the contents of a dataset, you call the Update method of a data adapter. The data adapter will execute the appropriate command (INSERT, UPDATE, or DELETE) based on the **RowState** of the row in the dataset.

> **Note** Because attempting to update a data source with the contents of a dataset can result in errors, you should invoke the data adapters **Update** method from within a **Try...Catch** block.

The exact procedure to update a data source can vary depending on your business needs, but your application should include the following steps:

1. Invoke the data adapters update method within a **Try...Catch** block.
2. If an exception is caught, locate the data row that caused the error. For more information, see Responding to Database Update Errors.
3. Reconcile the problem in the data row (programmatically if possible, or by presenting the erroneous row to the user for modification), and then reattempt the update.

To update a data source with a dataset

- Call the **Update** method of a data adapter, passing the name of the dataset that contains the values to be written to the data source.

  The following example shows how to attempt an update to a data source from within a **Try...Catch** block with the contents of `myDataset`.

```
' Visual Basic
Try
   oleDbDataadapter1.Update(myDataset)
Catch x As Exception
   ' Error during Update, add code to locate error, reconcile
   ' and try to update again.
End Try

// C#
try
{
   oleDbDataAdapter1.Update(myDataset);
}
catch (Exception e)
{
   // Error during Update, add code to locate error, reconcile
   // and try to update again.
}
```

Updating Related Tables in a Dataset

When updating related tables in a dataset, it is important to update in the proper sequence to reduce the chance of violating referential integrity constraints. The order of command execution will also follow the indices of the DataRowCollection in the dataset. To prevent data integrity errors from being raised, the best practice is to update the data source in the following sequence:

1. Child table: delete records.
2. Parent table: insert, update, and delete records.
3. Child table: insert and update records.

To update a data source with a dataset that contains two or more related tables

- Call the **Update** method of each data adapter.

  The following example shows how to update a data source with a dataset that contains related tables. In order to follow the

above sequence, three temporary DataTables will be created to hold the differing records. Then the **Update** method will be called for each subset of rows from within a **Try...Catch** block. If update errors occur, the suggested course of action is to branch off and resolve them. Then the dataset commits the changes. Finally, dispose of the temporary datatables to release the resources.

```
' Visual Basic
Private Sub UpdateDB()
    Dim DeletedChildRecords As DataTable = _
        DsNorthwind1.Orders.GetChanges(DataRowState.Deleted)
    Dim NewChildRecords As DataTable = _
        DsNorthwind1.Orders.GetChanges(DataRowState.Added)
    Dim ModifiedChildRecords As DataTable = _
        DsNorthwind1.Orders.GetChanges(DataRowState.Modified)
    Try
        If Not DeletedChildRecords Is Nothing Then
            daOrders.Update(DeletedChildRecords)
            DeletedChildRecords.Dispose()
        End If
        daCustomers.Update(DsNorthwind1, "Customers")
        If Not NewChildRecords Is Nothing Then
            daOrders.Update(NewChildRecords)
            NewChildRecords.Dispose()
        End If
        If Not ModifiedChildRecords Is Nothing Then
            daOrders.Update(ModifiedChildRecords)
            ModifiedChildRecords.Dispose()
        End If
        DsNorthwind1.AcceptChanges()
    Catch ex As Exception
        ' Update error, resolve and try again
    End Try
End Sub

// C#
void UpdateDB()
{
    DataTable DeletedChildRecords = dsNorthwind1.Orders.GetChanges(DataRowState.Deleted);
    DataTable NewChildRecords = dsNorthwind1.Orders.GetChanges(DataRowState.Added);
    DataTable ModifiedChildRecords = dsNorthwind1.Orders.GetChanges(DataRowState.Modified
);
    try
    {
        if (DeletedChildRecords != null)
        {
            daOrders.Update(DeletedChildRecords);
            DeletedChildRecords.Dispose();
        }
        if (NewChildRecords != null)
        {
            daOrders.Update(NewChildRecords);
            NewChildRecords.Dispose();
        }
        if (ModifiedChildRecords != null)
        {
            daOrders.Update(ModiifiedChildRecords);
            ModifiedChildRecords.Dispose();
        }
        DsNorthwind1.AcceptChanges();
    }
```

```
    catch (Exception ex)
    {
        // Update error, resolve and try again
    }
}
```

Responding to Database Update Errors

Errors may arise when attempting to update data. A typical error is that the record in the database has changed since it was read into your dataset. Regardless of what caused the error, you must create logic to handle the reconciliation of the record.

In order to resolve the row that raised the error, your application should locate the data row that caused the error, reconcile the problem, clear the error, and re-attempt the update. For more information, see Locating Rows that Have Errors.

When an update command has been executed, the data adapters **RowUpdated** event is raised for each record affected. By writing an event handler for this event, you can determine whether the update was successful. You can also set the **Status** property to determine whether the Update command should try to continue processing additional changes, or abort after an error is raised.

To respond to an update error

1. Create an event handler for the **RowUpdated** event. For more information, see Writing Event Handlers.
2. Check the **Status** property of the **RowUpdated** event.

   Note If there is an error, the value will be **ErrorsOccurred**.

3. If you want to control whether the update continues or not, set the **Status** property to a valid value as defined in the UpdateStatus Enumeration.You can also set the **IgnoreUpdateErrors** property of the data adapter.
4. Optionally, set the **RowError** property of the current row in the event object by assigning a value to it. This information is picked up by the dataset's **HasErrors** property.

   The following example illustrates how you can test whether a row was successfully updated within the **RowUpdated** event handler. If errors exist, the **RowError** property of the offending data row is set to the message of the error which automatically sets the **HasErrors** property to **true**. At this point you can handle the error based on the type of error raised as well as the needs of your application. Additionally you can set the **Status** property to continue processing the update, skip the remaining rows, or skip the current row.

```
' Visual Basic
Private Sub OleDbDataAdapter1_RowUpdated(ByVal sender As Object, _
ByVal e As System.Data.OleDb.OleDbRowUpdatedEventArgs) _
Handles OleDbDataAdapter1.RowUpdated
   If e.Status = UpdateStatus.ErrorsOccurred Then
      e.Row.RowError = e.Errors.Message
      ' Add code to reconcile the error.
   End If
End Sub

// C#
private void oleDbDataAdapter1_RowUpdated(object sender, System.Data.OleDb.OleDbRowUpdate
dEventArgs e)
{
   if (e.Status == UpdateStatus.ErrorsOccurred)
   {
      e.Row.RowError = e.Errors.Message;
      // Add code to reconcile the error.
   }
}
```

Concurrency Control in ADO.NET

Concurrency control is the process used to identify and resolve updates to data that are made by multiple users simultaneously. The following topics explain common methods of concurrency control, as well as specific ADO.NET features for handling concurrency errors.

In This Section

Introduction to Data Concurrency in ADO.NET
Provides an overview of the different methods of concurrency control.
Walkthrough: Handling a Concurrency Exception
Provides step-by-step instructions for identifying and resolving a concurrency error.
Implementing Optimistic Concurrency with Dynamic SQL
Describes how to configure an ADO.NET data adapter to automatically create SQL commands to identify and raise concurrency errors.
Implementing Optimistic Concurrency with Stored Procedures
Describes how to configure an ADO.NET data adapter to automatically create stored procedures that will identify and raise concurrency errors.
Handling Concurrency Errors
Describes how to use the **DBConcurrencyException** object to identify concurrency exceptions and the actual record that caused the error.
Transactions in ADO.NET
Provides an overview of data transactions in ADO.NET.

Related Sections

Optimistic Concurrency
Defines optimistic concurrency and the different approaches for implementing it.
DBConcurrencyException Class
Describes the **DBConcurrencyException** class and provides links to its members.
Performing Transactions
Details how to programmatically create and execute a data transaction.

Introduction to Data Concurrency in ADO.NET

When multiple users attempt to modify data at the same time, controls need to be established in order to prevent one user's modifications from adversely affecting modifications from simultaneous users. The system of handling what happens in this situation is called *concurrency control*.

Types of Concurrency Control

In general, there are three common ways to manage concurrency in a database:

- **Pessimistic concurrency control** - a row is unavailable to users from the time the record is fetched until it is updated in the database.
- **Optimistic concurrency control** - a row is unavailable to other users only while the data is actually being updated. The update examines the row in the database and determines whether any changes have been made. Attempting to update a record that has already been changed results in a concurrency violation.
- **"Last in wins"** - a row is unavailable to other users only while the data is actually being updated. However, no effort is made to compare updates against the original record; the record is simply written out, potentially overwriting any changes made by other users since you last refreshed the records.

Pessimistic Concurrency

Pessimistic concurrency is typically used for two reasons. First, in some situations there is high contention for the same records. The cost of placing locks on the data is less than the cost of rolling back changes when concurrency conflicts occur.

Pessimistic concurrency is also useful for situations where it is detrimental for the record to change during the course of a transaction. A good example is an inventory application. Consider a company representative checking inventory for a potential customer. You typically want to lock the record until an order is generated, which would generally flag the item with a status of ordered and remove it from available inventory. If no order is generated, the lock would be released so that other users checking inventory get an accurate count of available inventory.

However, pessimistic concurrency control is not possible in a disconnected architecture. Connections are open only long enough to read the data or to update it, so locks cannot be sustained for long periods. Moreover, an application that holds onto locks for long periods is not scalable.

> **Note** If your underlying data source supports transactions, you can simulate pessimistic concurrency by updating your data within a transaction. For more information, see Transactions in ADO.NET.

Optimistic Concurrency

In optimistic concurrency, locks are set and held only while the database is being accessed. The locks prevent other users from attempting to update records at the same instant. The data is always available except for the exact moment that an update is taking place. For more information, see Optimistic Concurrency.

When an update is attempted, the original version of a changed row is compared against the existing row in the database. If the two are different, the update fails with a concurrency error. It is up to you at that point to reconcile the two rows, using business logic that you create.

Last in Wins

With "last in wins," no check of the original data is made and the update is simply written to the database. It is understood that the following scenario can occur:

- User A fetches a record from the database.
- User B fetches the same record from the database, modifies it, and writes the updated record back to the database.
- User A modifies the 'old' record and writes it back to the database.

In the above scenario, the changes User B made were never seen by User A. Be sure that this situation is acceptable if you plan to use the "last in wins" approach of concurrency control.

Concurrency Control in ADO.NET and Visual Studio .NET

ADO.NET and Visual Studio .NET use optimistic concurrency, because the data architecture is based on disconnected data. Therefore, you need to add business logic to resolve issues with optimistic concurrency.

If you choose to use optimistic concurrency, there are two general ways to determine if changes have occurred: the version approach (true version numbers or date-time stamps) and the saving all values approach.

Version Number Approach

In the version number approach, the record to be updated must have a column that contains a date-time stamp or version number. The date-time stamp or a version number is saved on the client when the record is read. This value is then made part of the update.

One way to handle concurrency is to update only if value in the WHERE clause matches the value on the record. The SQL representation of this approach is:

```
UPDATE Table1 SET Column1 = @newvalue1, Column2 = @newvalue2
WHERE DateTimeStamp = @origDateTimeStamp
```

Alternatively, the comparison can be made using the version number:

```
UPDATE Table1 SET Column1 = @newvalue1, Column2 = @newvalue2
WHERE RowVersion = @origRowVersionValue
```

If the date-time stamps or version numbers match, the record in the data store has not changed and can be safely updated with the new values from the dataset. An error is returned if they don't match. You can write code to implement this form of concurrency checking in Visual Studio .NET. You will also have to write code to respond to any update conflicts. To keep the date-time stamp or version number accurate, you need to set up a trigger on the table to update it when a change to a row occurs.

Saving All Values Approach

An alternative to using a date-time stamp or version number is to get copies of all the fields when the record is read. The DataSet object in ADO.NET maintains two versions of each modified record: an original version (that was originally read from the data source) and a modified version, representing the user updates. When attempting to write the record back to the data source, the original values in the data row are compared against the record in the data source. If they match, it means that the database record has not changed since it was read. In that case, the changed values from the dataset are successfully written to the database.

Each data adapter command has a parameters collection for each of its four commands (DELETE, INSERT, SELECT, and UPDATE). Each command has parameters for both the original values, as well as the current (or modified) values.

> **Note** Adding new records (the INSERT command) only requires the current values since no original record exists and removing records (the DELETE command) only requires the original values in order to locate the record to delete.

The following example shows the command text for a dataset command that updates a typical Customers table. The command is specified for dynamic SQL and optimistic concurrency.

```
UPDATE Customers SET CustomerID = @currCustomerID, CompanyName = @currCompanyName, ContactNam
e = @currContactName,
       ContactTitle = currContactTitle, Address = @currAddress, City = @currCity,
       PostalCode = @currPostalCode, Phone = @currPhone, Fax = @currFax
WHERE (CustomerID = @origCustomerID) AND (Address = @origAddress OR @origAddress IS NULL AND
Address IS NULL) AND (City = @origCity OR @origCity IS NULL AND City IS NULL)
      AND (CompanyName = @origCompanyName OR @origCompanyName IS NULL AND CompanyName IS NULL
) AND (ContactName = @origContactName OR @origContactName IS NULL AND ContactName IS NULL) AN
D (ContactTitle = @origContactTitle OR @origContactTitle IS NULL AND ContactTitle IS NULL)
      AND (Fax = @origFax OR @origFax IS NULL AND Fax IS NULL) AND (Phone = @origPhone OR @or
igPhone IS NULL AND Phone IS NULL) AND (PostalCode = @origPostalCode OR @origPostalCode IS NU
LL AND PostalCode IS NULL);
SELECT CustomerID, CompanyName, ContactName, ContactTitle, Address, City,
       PostalCode, Phone, Fax
FROM Customers WHERE (CustomerID = @currCustomerID)
```

Note that the nine SET statement parameters represent the current values that will be written to the database, whereas the nine WHERE statement parameters represent the original values that are used to locate the original record.

The first nine parameters in the SET statement correspond to the first nine parameters in the parameters collection. These parameters would have their **SourceVersion** property set to **Current**.

The next nine parameters in the WHERE statement are used for optimistic concurrency. These placeholders would correspond to the next nine parameters in the parameters collection, and each of these parameters would have their **SourceVersion** property set to **Original**.

The SELECT statement is used to refresh the dataset after the update has occurred. It is generated when you set the **Refresh the DataSet** option in the **Advanced SQL Generations Options** dialog box.

> **Note** The above SQL uses named parameters, whereas **OleDbDataAdapter** commands use question marks (?) as parameter placeholders.

By default Visual Studio will create these parameters for you if you select the Optimistic Concurrency option in the DataAdapter Configuration Wizard. It is up to you to add code to handle the errors based upon your own business requirements. ADO.NET provides a DBConcurrencyException object that returns the row that violates the concurrency rules. For more information, see Handling Concurrency Errors.

Walkthrough: Handling a Concurrency Exception

In this walkthrough you will create a Windows application that raises a concurrency error and illustrates one strategy for handling it. The walkthrough simulates two users working with the same data at the same time. The Windows Form you will create allows you to act as both users from a single form.

This walkthrough will demonstrate the following tasks:

1. User 1 and User 2 fill there respective datasets with the same data.
2. User 2 edits a record, updates the dataset, and writes the changes to the data source.
3. User 1 edits the same record, updates the dataset, and attempts to write the changes to the data source, which results in a concurrency error being raised.

You will catch the error, then display the different versions of the record, allowing the user (you) to determine what should happen with the pending changes made by User 1.

> **Note** Using a dataset is only one option for data access, and is not the optimal choice in some scenarios. Nonetheless, datasets are usually the right choice in Windows Forms applications, and this walkthrough illustrates one scenario in which datasets are an appropriate choice. For more information, see Recommendations for Data Access Strategies.

Prerequisites for this walkthrough:

- Access to the Pubs SQL Server sample database with permission to perform updates.

Create a New Project and Data Connection

You begin your walkthrough by creating a new Windows application in Visual Basic or Visual C#.

To create a new project

1. From the **File** menu, point to **New**, and then click **Project** to display the **New Project** dialog box.
2. Depending on what language you want to use, select **Visual Basic Projects** or **Visual C# Projects** in the **Project Types** pane, and then select **Windows Application**.
3. Name the project **ConcurrencyWalkthrough**, then click **OK**.

   Visual Studio will add the ConcurrencyWalkthrough project to Solution Explorer and display a new Windows Form in the designer.

To create a new data connection

1. In Server Explorer, create a new connection to the Pubs sample database. For more information, see Adding New Data Connections in Server Explorer.

   > **Security Note** Storing connection-string details (such as the server name, user name, and password) can have implications for the security of your application. Using Windows Integrated Security is a more secure way to control access to a database. For more information, see Database Security.

2. In Server Explorer, expand the connection you created in the previous step.
3. Expand the **Tables** area.
4. Drag the **authors** table onto your form.

   A **Connection** object and a **DataAdapter** object appear in the component tray below the form.

Create the Datasets

In this section you will create two datasets named **DsAuthors1** and **DsAuthors2**. These datasets will represent the data that the two simultaneous users are working with. Next you will add two DataGrid controls to the form and bind them to the datasets. Finally, two Button controls will be added to the form: an **Update** button and a **Reset** button. The **Update** button will change a record in **DsAuthors1** and attempt to write the change to the database. The **Reset** button resets the database back to the original record so the walkthrough will work if run more than once.

To create two new datasets

1. Select the **DataAdapter** object.
2. From the **Data** menu, select **Generate Dataset**.

   The **Generate Dataset** dialog box appears.

3. Select **New** and name the dataset **DsAuthors**.

   An instance named **DsAuthors1** appears in the component tray.

4. From the **Data** tab of the Toolbox, drag a **DataSet** onto the form.

   The **Add Dataset** dialog box appears.

5. Confirm that **Typed dataset** is selected and **ConcurrencyWalkthrough.DsAuthors** appears in the **Name** box.

   An instance named **DsAuthors2** appears in the component design tray.

Bind the Data and Add Buttons

The data grids are used only to display the data. No data should be edited in the data grids during this walkthrough.

To add two DataGrids to the form

1. From the **Windows Forms** tab of the Toolbox, drag a **DataGrid** object onto the left side of your form.
2. From the **Windows Forms** tab of the Toolbox, drag a **DataGrid** object onto the right side of your form.

To bind the datasets to the DataGrid Controls

1. Select **DataGrid1** and set the following properties in the Properties window:

Property	Setting
DataSource	**DsAuthors1**
DataMember	**authors**
CaptionText	**DsAuthors1**

2. Select **DataGrid2** and set the following properties in the Properties window:

Property	Setting
DataSource	**DsAuthors2**
DataMember	**Authors**
CaptionText	**DsAuthors2**

To add the Update and Reset buttons to the form

1. From the **Windows Forms** tab of the Toolbox, drag a **Button** control onto the from and place it above **DataGrid1**.
2. With the button selected, in the Properties window name the button **btnUpdate** and set its **Text** property to **Update**.
3. From the **Windows Forms** tab of the Toolbox, drag a second **Button** object onto the from and place it above **DataGrid2**.
4. With the button selected in the Properties window, name the button **btnReset** and set its **Text** property to **Reset**.

Reset the Database

You will add code to the form that will reset the database to known values (in case you want to run the walkthrough more than once).

To add code to reset the database

- Right-click the form, choose **View Code** from the shortcut menu, and then insert the following code:

```
' Visual Basic
Private Sub resetDatabase()
   ' Fill the DsAuthors1 dataset with data.
   SqlDataAdapter1.Fill(DsAuthors1)
   ' Reset the au_fname in the first row to 'John'.
   DsAuthors1.authors(0).au_fname = "John"
   ' Write the record back to the database.
   SqlDataAdapter1.Update(DsAuthors1)
End Sub
```

```
// C#
private void resetDatabase()
{
   // Fill the dsAuthors dataset with data.
   sqlDataAdapter1.Fill(dsAuthors1);
   // Reset the au_fname in the first row to "John".
   dsAuthors1.authors[0].au_fname = "John";
   // Write the record back to the database.
   sqlDataAdapter1.Update(dsAuthors1);
}
```

Fill the Datasets

This step fills both datasets with the same data.

To add code to fill the datasets from the database

- Insert the following code into the Code Editor:

```
' Visual Basic
Private Sub FillTheDataSets()
   SqlDataAdapter1.Fill(DsAuthors1)
   SqlDataAdapter1.Fill(DsAuthors2)
End Sub

// C#
private void FillTheDataSets()
{
   sqlDataAdapter1.Fill(dsAuthors1);
   sqlDataAdapter1.Fill(dsAuthors2);
}
```

Simulate Changes by User 2

To add code to simulate changes by User 2

- Insert the following code into the Code Editor:

```
' Visual Basic
Private Sub user2changes()
   ' Simulate a second user changing a record.
   DsAuthors2.authors(0).au_fname = "User 2"
   ' Write it back to the database.
   SqlDataAdapter1.Update(DsAuthors2.GetChanges())
   ' Refresh DsAuthors2 with the updated data.
   SqlDataAdapter1.Fill(DsAuthors2)
End Sub

// C#
private void user2changes()
{
   // Simulate a second user changing a record.
   dsAuthors2.authors[0].au_fname = "User 2";
   // Write it back to the database.
   sqlDataAdapter1.Update(dsAuthors2.GetChanges());
   // Refresh dsAuthors2 with the updated data.
   sqlDataAdapter1.Fill(dsAuthors2);
}
```

Create the Form_Load Event Handler

To add code into the Form_Load event to initialize the walkthrough

1. Double-click an empty area of the form to automatically create the **Form_Load** event handler.
2. Add code so the event handler looks like the following:

```
' Visual Basic
Private Sub Form1_Load(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles MyBase.Load
   resetDatabase()
   FillTheDataSets()
   user2changes()
End Sub

// C#
private void Form1_Load(object sender, System.EventArgs e)
{
   resetDatabase();
   FillTheDataSets();
   user2changes();
}
```

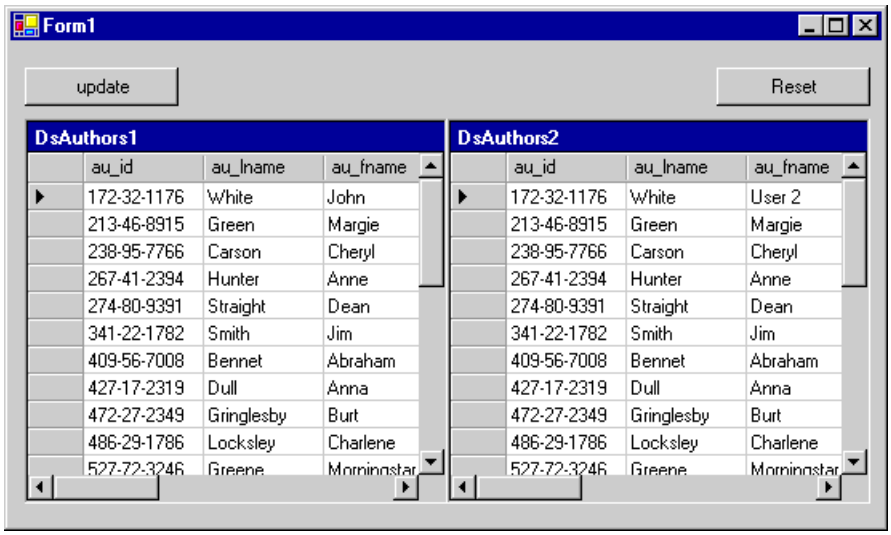
3. Save your project.

Run the Application

1. Press **F5** to run the application

   The form appears with two datagrids filled with data from the authors table in the Pubs database. The `au_fname` field of the first record in DsAuthors1 should be **John**. The `au_fname` field of the first record in DsAuthors2 should be **User 2**.

   Your form will look similar to the following:



2. From the **Debug** menu, select **Stop Debugging**.

Update the Dataset and Write the Changes to the Database

Next, you will write code that will attempt to update the database with changes from the **DsAuthors1** dataset. If successful, the AcceptChanges method of the dataset is called and a message box displays a success message. If the update fails for any reason, the error is caught and a message box displays the error message, with the type of error object as the title of the message box. Because this walkthrough is designed to raise a concurrency error, the successful message box is shown for completeness.

> **Note** This **Try...Catch** block will catch any error. Later in this walkthrough you will add an additional catch statement to specifically handle the concurrency error.

To update the database

1. Call the Update method.

2. Create an exception handler that displays a message box.

Your code should look like this:

```
' Visual Basic
Private Sub updateDatabase()
    Try
        ' Update the database with the changes from DsAuthors1.
        SqlDataAdapter1.Update(DsAuthors1.GetChanges)
        DsAuthors1.AcceptChanges()
        MessageBox.Show("The update was successful!")
    Catch ex As Exception
        ' Display information about update errors.
        MessageBox.Show("Update Failed", ex.GetType.ToString)
    End Try
End Sub

// C#
private void updateDatabase()
{
    try
    {
        // Update the database with the changes from dsAuthors1.
        sqlDataAdapter1.Update(dsAuthors1.GetChanges());
        dsAuthors1.AcceptChanges();
        MessageBox.Show("The update was successful.");
    }
    catch (Exception ex)
    {
        // Display information about update errors.
        MessageBox.Show("Update Failed", ex.GetType().ToString());
    }
}
```

Next, you will add code that changes the au_fname column in the DsAuthors1 dataset. The code then calls the **updateDatabase** procedure to try to write this change to the database. Because the value was changed earlier by User 2, a concurrency error will be raised.

To update the DsAuthors1 dataset

1. Double-click the **Update** button.
2. Create the **btnUpdate_Click** event handler**:**

```
' Visual Basic
Private Sub btnUpdate_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles btnUpdate.Click
   ' Change au_fname in the first row of DsAuthors1 to User 1.
   DsAuthors1.authors(0).au_fname = "User 1"
   updateDatabase()
End Sub

// C#
private void btnUpdate_Click(object sender, System.EventArgs e)
{
    // Change au_fname in the first row of dsAuthors1 to "User 1".
    dsAuthors1.authors[0].au_fname = "User 1";
    updateDatabase();
}
```

3. Save your project.
4. Press **F5** to run the application.
5. Click the **Update** button to change the **au_fname** field of the first record to **User 1**.

   The concurrency error will be raised.

Handling Concurrency Errors

How you handle the error is dependent upon the specific business rules that govern your application. The following strategy to handle the error will be used as an illustration. The application will present the user with three versions of the record:

- The current record in the database
- The original record in the dataset
- The proposed changes in the dataset

The user will then be able to either overwrite the database with the proposed change or cancel the update and refresh the dataset.

Creating a Custom Error Handler

When you perform an update, you generally want to do so in a structured exception handler so that you can catch errors. In the code you used above, you used a **try...catch** block that caught all errors — that is, a structure that includes a generic **catch** statement for any error.

You can also catch specific errors, so that you can respond appropriately. To illustrate, this walkthrough will add an exception handler for one specific error — namely, a concurrency error, which you can examine using the DbConcurrencyException object. Here, you will handle this error by displaying information to the user.

To add specific handling for the DBConcurrencyException error

1. If the application is still running, exit run mode to return to the Code Editor.
2. Add a second **catch** statement above the existing one in the **updateDatabase** method.
3. Pass the **DBConcurrencyException** object to the `createMessage` procedure, which you will create in the next section.

```
' Visual Basic
Private Sub updateDatabase()
    Try
        ' Update the database with the changes from dsAuthors1.
        SqlDataAdapter1.Update(DsAuthors1.GetChanges())
        DsAuthors1.AcceptChanges()
        MessageBox.Show("The update was successful!")
    Catch dbcx As DBConcurrencyException
        createMessage(dbcx)
    Catch ex As Exception
        MessageBox.Show("Update Failed", ex.GetType().ToString())
    End Try
End Sub

// C#
private void updateDatabase()
{
    try
    {
        // Update the database with the changes from dsAuthors1.
        sqlDataAdapter1.Update(dsAuthors1.GetChanges());
        dsAuthors1.AcceptChanges();
        MessageBox.Show("The update was successful!");
    }
    catch (DBConcurrencyException dbcx)
    {
        createMessage(dbcx);
    }
    catch (Exception ex)
    {
        MessageBox.Show("Update Failed", ex.GetType().ToString());
    }
```

}

Displaying Choices to the User

The code you just wrote calls the `createMessage` procedure to display error information to the user. For this walkthrough, you will use a message box to display the different versions of the record to the user and allow the user to choose whether to overwrite the record with new changes or cancel the edit.

> **Note** For simplicity's sake, this walkthrough uses the second dataset (DsAuthors2) as the data source for fetching the current record in the database. In a real-world application you would requery the actual data source to fetch the current value of the record that raised the error.

To create the createMessage procedure

- Create the error handler by adding the following code to the Code Editor:

```
' Visual Basic
Private Sub createMessage(ByVal dbcx As DBConcurrencyException)
   ' Declare variables to hold the row versions for display
   ' in the message box.
   Dim strInDs As String = "Original record in DsAuthors1:" _
      & ControlChars.CrLf
   Dim strInDB As String = "Current record in database:" _
      & ControlChars.CrLf
   Dim strProposed As String = "Proposed change:" & ControlChars.CrLf
   Dim strPromptText As String = "Do you want to overwrite the current record in the data
base with the proposed change?" & ControlChars.CrLf
   Dim strMessage As String
   Dim response As System.Windows.Forms.DialogResult

   ' Locate the current record in the data source that caused the exception
   Dim rowInDB As DataRow = _
      DsAuthors2.authors.FindByau_id(CType(dbcx.Row("au_id"), String))

   ' Loop through the column values.
   Dim i As Integer
   For i = 0 To dbcx.Row.ItemArray.Length - 1
      strInDs &= dbcx.Row(i, DataRowVersion.Original) & _
         ControlChars.Tab
      strInDB &= rowInDB(i, DataRowVersion.Current) & ControlChars.Tab
      strProposed &= dbcx.Row(i, DataRowVersion.Current) & _
         ControlChars.Tab
   Next

   ' Create the message box text string.
   strMessage = strInDs & ControlChars.CrLf
   strMessage &= strInDB & ControlChars.CrLf
   strMessage &= strProposed & ControlChars.CrLf
   strMessage &= strPromptText

   ' Display the message box.
   response = MessageBox.Show(strMessage, "Update Failed", _
      MessageBoxButtons.YesNo)
   processResponse(response)
End Sub

// C#
private void createMessage(DBConcurrencyException dbcx)
{
    // Declare variables to hold the row versions for display
    // in the message box.
    string strInDs = "Original record in dsAuthors1:\n";
```

```
    string strInDB = "Current record in database:\n";
    string strProposed = "Proposed change:\n";
    string strPromptText = "Do you want to overwrite the current " +
      "record in the database with the proposed change?\n";
    string strMessage;
    System.Windows.Forms.DialogResult response;

    // Loop through the column values.
   DataRow rowInDB =
      dsAuthors2.authors.FindByau_id(dbcx.Row["Au_ID"].ToString());
   for (int i = 0; i < dbcx.Row.ItemArray.Length; i++)
   {
      strInDs += dbcx.Row[i, DataRowVersion.Original] + "\n";
      strInDB += rowInDB[i, DataRowVersion.Current] + "\n";
      strProposed += dbcx.Row[i, DataRowVersion.Current] + "\n";
   }

    // Create the message box text string.
    strMessage = strInDs + "\n" + strInDB + "\n" + strProposed + "\n"
        + strPromptText;

    // Display the message box.
    response = MessageBox.Show(strMessage, "Update Failed",
       MessageBoxButtons.YesNo);
    processResponse(response);
}
```

Processing the User's Response

You will also need code to process the user's response to the message box. The options are either to overwrite the current record in the database with the proposed change or not. If the user chooses yes, the Merge method of **DsAuthors1** is called with the *preserveChanges* argument set to **true**. This takes the original versions of the data rows in **DsAuthors2** and merges them with the current versions of data rows in **DsAuthors1**. This will cause the update attempt to be successful, because the original version of the record now matches the database.

To process the user input from the message box

- Add the following code to the Code Editor:

```
' Visual Basic
Private Sub processResponse(ByVal response As _
System.Windows.Forms.DialogResult)
   ' Execute the appropriate code depending on the button
   ' selected in the message box.
   Select Case response
      Case System.Windows.Forms.DialogResult.Yes
         ' Overwrite the database with the proposed record.
         DsAuthors1.Merge(DsAuthors2, True)
         SqlDataAdapter1.Update(DsAuthors1)
         DsAuthors1.AcceptChanges()
      Case System.Windows.Forms.DialogResult.No
         ' Cancel proposed changes and refresh DsAuthors1.
         DsAuthors1.Merge(DsAuthors2)
   End Select
End Sub

// C#
private void processResponse(
System.Windows.Forms.DialogResult response)
{
```

```
    // Execute the appropriate code depending on the button selected
    // in the message box.
    switch (response)
    {
        case System.Windows.Forms.DialogResult.Yes :
            // Overwrite the database with the proposed record.
            dsAuthors1.Merge(dsAuthors2, true);
            sqlDataAdapter1.Update(dsAuthors1);
            dsAuthors1.AcceptChanges();
            break;
        case System.Windows.Forms.DialogResult.No :
            // Cancel proposed changes and refresh dsAuthors1.
            dsAuthors1.Merge(dsAuthors2);
            break;
    }
}
```

Resetting the Data

To reset the form, the **Form1_Load** method will be modified to execute when the **Reset** button is clicked. Because Visual Basic and Visual C# have different event models, there are different ways to associate an event handler with an event.

> **Note** One method can be the event handler for multiple events of multiple objects. For more information, see Connecting Multiple Events to a Single Event Handler in Windows Forms.

To create an event handler for the btnReset button with Visual Basic

1. In the Code Editor, locate the **Form_Load** event handler.
2. Insert a comma and then **btnReset.Click** to the end of the handler to make the **Form1_Load** method the event handler for the **Click** event of `btnReset`.

```
Private Sub Form1_Load(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles MyBase.Load, btnReset.Click
   resetDatabase()
   FillTheDataSets()
   user2changes()
End Sub
```

To create an event handler for the btnReset button with Visual C#

1. Open the form in the designer.
2. Click the **Reset** button.
3. In the Properties window, click the **Events** button in the Properties window toolbar.
4. Locate the **Click** event, and then click the arrow to see all the methods that could respond to the event.

   In this case, **Form1_Load** appears because it has the the right signature for a **button.click** event.

5. Select **Form1_Load**.

   The code to associate the Form1_Load method with the **btnReset.Click** event is automatically generated. **Form1_Load** now responds to both **Form1.Load** and **btnReset.Click**.

   > **Tip** To view the generated code, double-click the form and expand the dimmed "Windows Form Designer generated code" section.

Run the Application

1. Press **F5** to run the application.
2. Click the **Update** button.

   The concurrency error will be raised, and the message box will appear.

Implementing Optimistic Concurrency with Dynamic SQL

Visual Studio can implement optimistic concurrency with dynamic SQL. Ultimately, this approach builds an SQL command string with a WHERE clause that contains all of the original data-store values. This string is then invoked as a SQL command on the data store. The WHERE clause will not return any records if changes have occurred to the record in the data store. These concurrency exceptions must be handled according to business needs.

To implement optimistic concurrency with dynamic SQL

1. If you do not already have a connection to a database, add one using Server Explorer. For more information, see Adding New Data Connections in Server Explorer.
2. Drag a table from Server Explorer onto the designer surface.

   You will get a **DataAdapter** object and a **Connection** object. If you are working with a Windows Application project, a component designer tray will appear at the bottom of the screen. This tray allows visual development of components that have no run-time user interface. If you started with an XML Web service, the entire main window will provide a component design surface.

3. Right-click the **DataAdapter**, and then select **Configure Data Adapter** to display the **Data Adapter Configuration Wizard**.
4. Click **Next** and then click **Next** again to bring up the **Choose a Query Type** page.
5. Make sure that **Use SQL statement** is selected, and then click **Next**.
6. In the **Generate the SQL Statements** page, click the **Query Builder** button.
7. In the **Query Builder**, select the fields you want.
8. Select the columns you want, and then click **OK**.
9. In the **Generate the SQL Statements** page, click the **Advanced Options** button and note that **Use optimistic concurrency** is selected by default.
10. Click **OK** and then **Finish** to complete the wizard.

You can inspect the results of the configuration by examining the three update-related data adapter command properties: **DeleteCommand**, **InsertCommand**, and **UpdateCommand**.

Optimistic Concurrency | Implementing Optimistic Concurrency with Stored Procedures | Handling Concurrency Errors

Implementing Optimistic Concurrency with Stored Procedures

Visual Studio can implement optimistic concurrency with stored procedures. Ultimately this approach builds an SQL command with a WHERE clause that contains all of the original data store values. Parameters that include the WHERE clause values are passed to a stored procedure within the data store. The WHERE clause will not return any records if changes have occurred to the data store. These changes can be handled according to business needs.

To implement optimistic concurrency with stored procedures

1. If you do not already have a connection to a database, add one. For more information, see Adding New Data Connections in Server Explorer.
2. Drag a table from Server Explorer onto the designer surface.

   You will get an adapter object and a connection object.

   > **Note** If you are working with a project that has an interface (such as a Windows application or a Web application), a component tray will appear at the bottom of the designer. This tray allows visual development of components that have no run-time user interface. If you are working with other project types (such as an XML Web service), the objects will appear on the Component Designer — that is, the entire main window will provide a component design surface.

3. Right-click the adapter object, and then select **Configure Data Adapter** from the shortcut menu to display the **Data Adapter Configuration Wizard**.
4. Click **Next** and then click **Next** again for the **Choose a Query Type** page.
5. Make sure that **Create new stored procedures** is selected, and then click **Next**.
6. In the **Generate the stored procedures** page, click the **Query Builder** button.
7. In the **Query Builder**, check the individual fields you want.

   > **Note** In the **Generate the stored procedures** page, click the **Advanced Options** button, and notice the **Use optimistic concurrency** option is selected by default.

8. Click **OK**, and then click **Next** to bring up the **Create the Stored Procedures** page.
9. In the **Create the Stored Procedures** page, assign names to each of the four stored procedures that will be generated, and you can have the wizard automatically create them in the database for you or choose to manually create them later. Click **Next** then **Finish** to complete the wizard.

You can inspect the results of the configuration by examining the three update-related data adapter command properties: the **DeleteCommand**, **InsertCommand**, and the **UpdateCommand**.

Optimistic Concurrency | Implementing Optimistic Concurrency with Dynamic SQL | Handling Concurrency Errors

Handling Concurrency Errors

ADO.NET provides a DBConcurrencyException object to assist in resolving issues arising from concurrency violations. The **DBConcurrencyException** object returns the data row that caused the error. For more information, see DBConcurrencyException Members.

The following example attempts to update a data source with the contents of `myDataset` from within a **Try...Catch** block, if an error is raised an error message along with the first column of the offending data row is displayed.

> **Note** The code below is an illustration of one strategy in handling a database update error. The code assumes several things; an existing connection to a database, an existing dataset named myDataset, as well as the assumption that execution of the update command will raise a concurrency violation. For more information and a complete example, see Walkthrough: Handling a Concurrency Exception.

To resolve a concurrency violation

1. Execute the command to update the database from within a **Try...Catch** block.
2. If an exception is raised, inspect the **Catch** statement's **Row** property to determine what caused the violation.
3. Add code to resolve the error based on your application's business rules.

   The following code uses SqlDataAdapter1 and myDataset as examples of the data adapter and dataset in your application.

```
' Visual Basic
Try
   SqlDataAdapter1.Update(myDataset)
Catch ex As DBConcurrencyException
   Dim customErrorMessage As String
   customErrorMessage = "Concurrency violation" & vbCrLf
   customErrorMessage += Ctype(ex.Row.Item(0), String)
   MessageBox.Show(customErrorMessage)
   ' Replace the above code with appropriate business logic
   ' to resolve the concurrency violation.
End Try

// C#
try
{
   SqlDataAdapter1.Update(myDataset);
}
catch (DBConcurrencyException ex)
{
   string customErrorMessage;
   customErrorMessage = "Concurrency violation\n";
   customErrorMessage += ex.Row[0].ToString();
   // Replace the above code with appropriate business logic
   // to resolve the concurrency violation.
}
```

Transactions in ADO.NET

Transactions are groups of database commands that execute as a package. Using a transaction gives your application the ability to abort (roll back) all changes executed from within the transaction if any errors occur during any part of the transaction process. For example, consider an application with two tables, where one table represents inventory and the other represents orders. When an order is added to one table, the corresponding inventory needs to reduced in the other table. If an update to the Orders table was successful and an update to the Inventory table failed, the integrity of your data would be compromised. In order to guarantee that both tables were updated successfully, you could package both data commands into a single transaction. If one table updated successfully and the other table did not, you can rollback the entire transaction, resolve the issues that caused the failure, and re-attempt the transaction again.

> **Note** Your underlying data source must support transactions in order to use the transaction features supported in Visual Studio .NET.

Transactions are created by calling the **BeginTransaction** method of a data connection object. For more information, see Performing Transactions.

XML Schemas and Data

XML plays a large role in the way data is handled in Visual Studio .NET. XML is used in the following ways:

- Datasets can serialize their data as XML. The schema of a dataset — what tables, columns, data types, and constraints are in the dataset — is defined using an XML Schema (.xsd file).
- You can infer XML Schemas from existing datasets and create datasets from existing XML Schemas.

Visual Studio makes working with XML files, XML Schemas, and ADO.NET datasets easy by providing you with a visual tool, the XML Designer.

The XML Designer is used to create and edit XML Schema files, ADO.NET datasets, XML data files, and XML source code. The XML Designer has three views:

- **Schema view** for visually editing XML Schemas and ADO.NET datasets.
- **Data view** with a structured data grid for visually editing XML data files.
- **XML view** with color-coding, IntelliSense, and statement completion for working directly with XML source code.

Introduction to XML Schemas

XML Schemas are documents that are used to define and validate the content and structure of XML data, just as a database schema defines and validates the tables, columns, and data types that make up a database.

An XML Schema defines and describes certain types of XML data by using the XML Schema definition language (XSD). XML Schema elements (elements, attributes, types, and groups) are used to define the valid structure, valid data content, and relationships of certain types of XML data. XML Schemas can also provide default values for attributes, and elements. For more information, see the World Wide Web Consortium (W3C) Web site (http://www.w3.org/).

You use an XML Schema to guarantee consistency among certain types of XML data that is shared between applications and organizations. An XML Schema can be used as a contract for data exchange between two applications. Organizations can publish schemas that describe the format of the XML their applications produce and consume. Other organizations and applications that wish to exchange data can then build their applications around these schemas so their xml messages will be understood.

For example, a purchase order represented in XML can be validated with an XML Schema before it is sent between buyer and seller. This validation verifies that all of the elements (individual pieces) of data exist, are in the expected sequence, and are all of the correct data type. This ensures that the recipient of the purchase order will be able to interpret the data correctly when it is received.

XML Schemas in Visual Studio conform to the W3C recommendation regarding XML Schema based on the XML Schema definition language (XSD). These are some of the advantages that XML Schemas have over previous technologies, such as DTDs:

- XML Schemas use XML syntax, so you do not need to learn a new syntax to define your data structure.
- XML Schemas support reusable types and allow you to create new types using inheritance.
- XML Schemas allows you to group elements to control the recurrence of elements and attributes.

For more information about schemas and how the elements they represent constrain data, see XML Elements, Attributes, and Types.

For more information about XML Schemas, see the XML Schema Reference (XSD) and MSDN Online XML Developer Center (http://msdn.microsoft.com/xml).

Introduction to Datasets

XML Technology Backgrounder

Extensible Markup Language (XML) provides a way to describe structured data. Unlike HTML tags, which are primarily used to control the display and appearance of data, XML tags are used to define the structure and data types of the data itself.

XML uses a set of tags to delineate elements of data. Each element encapsulates a piece of data that may be very simple or very complex. You can define an unlimited set of XML tags. For example, you might define XML tags to declare pieces of data from a purchase order, such as the price, tax, shipping address, billing address, and so on. As XML tags are adopted throughout an organization and across organizations, data from all kinds of different data stores will be easier to exchange and manipulate.

XML is simple, platform-independent, and a widely adopted standard. The advantage of XML over HTML is that it separates the user interface from the structured data. This separation of data from presentation enables the integration of data from diverse sources. Customer information, purchase orders, research results, bill payments, medical records, catalog data, and other information can be converted to XML.

XML vs. HTML

The following are a few important points to keep in mind about the relationship between XML and HTML:

- XML is not a replacement for HTML; in fact, XML can be considered a complement to HTML. XML and HTML have different goals: HTML is designed to display data and is focused on how data looks, while XML is designed to describe data and to focus on what data is.
- Like HTML, XML does not do anything. While XML tags can be used to describe the structure of an item such as a purchase order, it does not contain any code that can be used to send that purchase order, process it, or ensure that it is filled. Other people must write code to actually do these things with your XML-formatted data.
- Unlike HTML, XML tags are defined by the author of a schema or document and are unlimited. HTML tags are predefined; HTML authors can only use tags that are supported by the current HTML standard.

Uses of XML

XML is an extremely flexible way to pass around data. The following are all examples where XML can be used:

- An ordinary document
- A structured record, such as an appointment record or purchase order
- Internet/intranet Web applications that move data
- An object with data, such as the persistent format of an object or ActiveX control
- A data record, such as the result set of a query
- Meta-content about a Web site, such as Channel Definition Format (CDF)
- Graphical presentation, such as an application's user interface
- Links between information and people on the Web
- C# code, which can be documented with XML; for more information, see XML Documentation
- Discovery documents used to locate available XML Web services; For more information, see XML Web Service Discovery.

The following lists several advantages XML has over other formats when storing information:

- XML formats are text-based, making them more readable, easier to document, and sometimes easier to debug.
- XML documents can use much of the infrastructure already built for HTML, including the HTTP protocol and some browsers. HTTP allows XML to be transferred across firewalls.
- XML parsing is well defined and widely implemented, making it possible to retrieve information from XML documents in a variety of environments.
- Applications can rely on XML parsers to do some structural validation, as well as data type checking (when schemas are used).
- XML is built on a Unicode foundation, making it easier to create internationalized documents.

XML is not appropriate for every situation, however. XML documents tend to be more verbose than the binary formats they replace. They take up more network bandwidth and storage space, or require more processor time for compression. XML parsing can be slower than parsing highly optimized binary formats and can require more memory. However, careful application design can avoid some of these problems.

Validating XML Documents

To validate that XML documents contain the desired data and structure, an XML Schema must be associated with the XML document. XML Schemas are the rules that define how elements and attributes are structured to form XML documents. You can share schemas between organizations to make it simple to transfer and process shared data. For more information, see Introduction to XML Schemas.

Displaying XML Data

There are several ways that can be used to display (or present) XML data.

There are even mechanisms of data binding that can be used along with style sheets to arrange XML data into a visual presentation and to add interactivity.

Among others, here are a few methods to display XML:

- XSLT – Extensible Style Sheet Language
- CSS – Cascading Style Sheets
- Microsoft Internet Explorer

For more information, see MSDN Online XML Developer Center Web site (http://msdn.microsoft.com/xml/default.asp).

XML Resources

If you are familiar with HTML, you can learn to create XML documents, requiring only that they be valid and well formed. For more information about XML, see the XML SDK and MSDN Online XML Developer Center Web site (http://msdn.microsoft.com/xml/default.asp).

For more information, see the World Wide Web Consortium (W3C) Specification for XML (http://www.w3.org/XML/).

XML Schema Syntax

The example XML Schema below contains the following items:

- The first statement, `<?xml version="1.0" encoding="utf-8"?>`, specifies the version of XML in use.
- The second statement consists of several parts:

  The `xs:schema` declaration indicates that this is a schema and that the xs: prefix will be used before schema items.

  The `xmlns:xs="http://www.w3.org/2001/XMLSchema"` declaration indicates that all tags in this schema should be interpreted according to the default namespace of the World Wide Web Consortium (W3C), which was created in 2001.

  The `targetnamespace` declaration names this schema as XMLSchema1.xsd and indicates its default location, which will be in a default URI (universal resource identifier) on your development server called tempuri.org.

  For more information about xmlns and targetnamespace, see schema Element.

  > **Note** When you create a schema with the XML Designer, the version and namespace statements are automatically added for you. You might modify the contents of these two declarations in some cases. For example, if you want to use a tag prefix other than "XS," you would need to define the default namespace for that tag in addition to the XS tag prefix.

- An unnamed complex type called "addressType" is defined that will contain five elements of various data types. Note that each of the elements it contains is a simple, named type.
- A complex element named "purchaseOrder" is defined. It contains elements that make use of the previously defined addressType. This creates a nested relationship between the purchaseOrder element and these elements.
- The final element in the purchaseOrder, Item, contains a facet called **maxOccurs**. Facets set limits on the type of content a simple type can contain. **maxOccurs** is used to constrain how many times an element can occur in the documents created from this schema. By default, **maxOccurs** is equal to one. In this case, setting it to unbounded indicates that the Item element can reoccur as many times as needed.

The following example shows a sample XML Schema:

```
<?xml version="1.0" encoding="utf-8"?>
<xs:schema targetNamespace="http://tempuri.org/XMLSchema1.xsd" xmlns:xs="http://www.w3.org/20
01/XMLSchema">
<xs:complexType name="addressType">
   <xs:sequence>
      <xs:element name="street1" type="xs:string"/>
      <xs:element name="street2" type="xs:string"/>
      <xs:element name="city" type="xs:string"/>
      <xs:element name="state" type="xs:string"/>
      <xs:element name="zip" type="xs:integer"/>
   </xs:sequence>
</xs:complexType>

<xs:element name="purchaseOrder">
      <xs:complexType>
         <xs:sequence>
            <xs:element name="shipTo" type="addressType" />
            <xs:element name="billTo" type="addressType" />
            <xs:element name="shipDate" type="xs:date" />
            <xs:element name="item" maxOccurs="unbounded"/>
         </xs:sequence>
      </xs:complexType>
   </xs:element>
</xs:schema>
```

XML Schemas and the XML Designer

XML Schemas are combinations of element, attribute, type, and group definitions; whereas ADO.NET typed datasets are classes that are defined by XML Schemas (.xsd files). XML Schemas in Visual Studio use the XML Schema definition language (XSD) that conforms to the recommendation for XML Schema of the World Wide Web Consortium (W3C). For more information about XML Schema, see XML Schema Reference (XSD).

This section will explain how to add new schema (.xsd) files to your project and how to create the individual pieces that XML Schemas are constructed of.

XML Designer

Overview of the XML Design tool in Visual Studio.

XML Elements, Attributes, and Types

The basic building blocks of XML Schemas are elements and attributes. Data types define the valid content that elements and attributes contain. When you create XML Schemas, you define the individual elements and attributes and assign valid types to them. Elements describe data, whereas attributes are like properties of an element, in that they provide further definition about the element the way that properties describe characteristics of objects and classes.

Elements

An element describes the data that it contains. Elements can also contain other elements and attributes. For more information, see element.

When an element definition contains additional elements or attributes, it is a complex type. For more information on complex types, see the "Types" section later in this topic.

A basic element definition consists of a name and a data type. The following example shows how to define an element named `quantity`, with a simple type value of integer.

```
<xs:element name="quantity" type="xs:integer" />
```

The element classifies the data — in this case as a quantity. The type defines the valid content that the element contains — in this case an integer.

The following example shows a valid instance of XML data that conforms to the `quantity` element defined in the previous example:

```
<quantity>63</quantity>
```

The following example shows an invalid instance of the quantity element:

```
<quantity>sixty three</quantity>
```

Attributes

An attribute is a named simple-type definition that cannot contain other elements. Attributes can also be assigned an optional default value and they must appear at the bottom of complex-type definitions. Additionally, if multiple attributes are declared, they may occur in any order. For more information, see attribute.

The following code shows how to declare an attribute named `OrderDiscount` that is defined with the simple type `number`. The use of an attribute makes sense here since attributes are optional. If no `OrderDiscount` is provided the XML data will still be valid.

```
<xs:element name="OrderInfo">
   <xs:complexType>
      <xs:sequence>
         <xs:element name="CustomerName" type="xs:string" />
         <xs:element name="OrderNumber" type="xs:positiveInteger" />
         <xs:element name="OrderTotal" type="xs:number" />
      </xs:sequence>
      <xs:attribute name="OrderDiscount" type="xs:number" />
   </xs:complexType>
</xs:element>
```

Naming Elements and Attributes

The following are a few relevant details about elements and attributes:

- XML is case-sensitive. Thus an element named "statecode" is different from an element named "stateCode."
- Attribute values must always be in quotation marks. For more information, see attribute.
- Element names cannot start with a number or underscore, or with the letters "XML."
- Element names cannot contain spaces.

Should I Use an Element or an Attribute?

Elements are used to encapsulate pieces of data, and attributes are generally used to provide accompanying information about an element, rather than to encapsulate raw data itself. Whether you actually use an element or an attribute is up to the needs of your application.

Use attributes if your information requires data of a simple type and:

- Your information requires a default or fixed value.
- Your information requires data that is metadata for an existing element
- If the size of your XML file is an issue, attributes tend to take up fewer bytes than elements

The following list describes the key differences between elements and attributes from a schema perspective:

- A schema can define whether the ordering of elements is significant, but attributes can occur in any order.
- Elements can be nested with the `<choice>` tag, which means one and only one of the listed elements can appear.
- Elements can occur more than once, but attributes cannot.

Types

Types in XML Schemas define the valid data type that elements or attributes may contain, and can be simple or complex. Additionally, types can be named or unnamed. For more information, see Named vs. Unnamed Types and Groups.

Simple Types

There are two major categories of simple types:

- *Built-in types*, which are defined by the World Wide Web Consortium's XML Schema specification - for example, **string, boolean**, and **float**.

  Built-in types include both primitive types and derived types.

  Primitive data types are not derived from other data types. For example, float is a mathematical concept that is not derived from other data types. For more information, see Primitive XML Data Types.

  Derived data types are defined in terms of existing data types. For example, integer is a special case derived from the decimal data type. For more information, see Derived XML Data Types.

- *User-defined simple types* are derived from the W3C built-in types by applying user-defined values to items called facets. For more information, see User-Defined Simple Types in XML Schemas.

Facets

Facets constrain the acceptable values of simple types. User-defined simple types can be created by applying facets. For more information, see Data Type Facets.

In the following example the `maxInclusive` facet is applied to a simple type named `qtyLimiter` in order to restrict the acceptable values of the `positiveInteger` type to quantities from 1 through 100:

```
<xs:simpleType name="qtyLimiter">
   <xs:restriction base="xs:positiveInteger">
      <xs:maxInclusive value="100" />
   </xs:restriction>
</xs:simpleType>
```

Complex Types

Complex types are element definitions that can include other elements, attributes, and groups. An important difference between complex and simple types is that complex types can include elements and attributes declared as simple or complex types, whereas simple types cannot include other elements, attributes, or groups but can only include facets. For more information, see Complex Types in XML Schemas.

element | attribute| Named vs. Unnamed Types and Groups | User-Defined Simple Types in XML Schemas | Element Groups | Attribute Groups |Creating XML Schemas and Datasets | Relational Data in XML Schemas |
Introduction to Data Access with ADO.NET | Introduction to Datasets

Named vs. Unnamed Types and Groups

Data types and groups in XML Schemas can be either named or unnamed. If you plan to reuse a data type within your schema, create a named type and refer to it in all the elements that require that data type. Named types can also make your schema easier to read.

Named Types

A named type is a *globally declared* data type that has a **name** attribute. Globally declared elements are direct children of the `<schema>` element, as opposed to being nested within other element definitions. The following example shows how to globally declare the complex type `usAddress`. The element `customerInfo` uses `usAddress` twice: as part of BillTo and ShipTo elements. The elements `name`, `city`, `ShipTo`, and so on, are all declared nested within definitions.

```
<?xml version="1.0" encoding="utf-8" ?>
<xs:schema id="XMLSchema1" xmlns:xs="http://www.w3.org/2001/XMLSchema">
   <xs:complexType name="usAddress">
      <xs:sequence>
         <xs:element name="name" type="xs:string" />
         <xs:element name="street" type="xs:string" />
         <xs:element name="city" type="xs:string" />
         <xs:element name="state" type="xs:string" />
         <xs:element name="zip" type="xs:string" />
      </xs:sequence>
   </xs:complexType>
   <xs:element name="customerInfo">
      <xs:complexType>
         <xs:sequence>
            <xs:element name="Name" type="xs:string" />
            <xs:element name="ShipTo" type="usAddress" />
            <xs:element name="BillTo" type="usAddress" />
         </xs:sequence>
      </xs:complexType>
   </xs:element>
</xs:schema>
```

In the XML Designer named types are declared by dragging a **simpleType**, **complexType,** or **group** from the XML Schema tab of the Toolbox onto the design surface. It is important to note that when creating unnamed types, the data type is defined within the design grid of an element, not within a **simpleType** or **complexType**.

Unnamed Types

An unnamed type is a data type that is nested (in-line) within the definition of an element. You could use an unnamed type when a type is only needed once within your schema.

In contrast with the preceding example, the following example shows how to define an address as an unnamed type — nested within the `ShipTo` element. In this schema, you know that you only need one address.

```
<?xml version="1.0" encoding="utf-8" ?>
<xs:schema id="XMLSchema1" xmlns:xs="http://www.w3.org/2001/XMLSchema">
   <xs:element name="customerInfo">
      <xs:complexType>
         <xs:sequence>
            <xs:element name="Name" type="xs:string" />
            <xs:element name="ShipTo">
               <xs:complexType>
                  <xs:sequence>
                     <xs:element name="name" type="xs:string" />
                     <xs:element name="street" type="xs:string" />
                     <xs:element name="city" type="xs:string" />
                     <xs:element name="state" type="xs:string" />
                     <xs:element name="zip" type="xs:string" />
                  </xs:sequence>
               </xs:complexType>
            </xs:element>
         </xs:sequence>
```

```
        </xs:complexType>
    </xs:element>
</xs:schema>
```

Creating Elements in XML Schemas

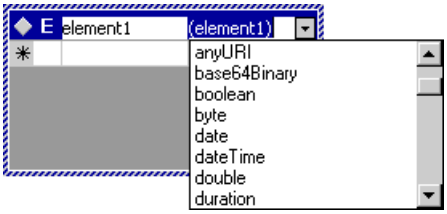
Elements are the basic building blocks of XML Schemas. Declaring an element involves associating a name with a data type. For more information, see XML Elements, Attributes, and Types.

For an overview of where elements fit into the process of creating an XML Schema, see
Creating XML Schemas: High-Level Process for a summary of the steps, and
Walkthrough: Creating an XML Schema with the XML Designer for step-by-step instructions for a representative scenario: creating a purchase-order schema.

Elements can be added to the following:

- Schema
- Other elements
- ComplexTypes
- Groups

Visual representation of an element in the XML Designer



To create an element with the XML Designer

1. Add an **XML Schema** or **Dataset** to your project. For more information, see Adding New Schemas.
2. Drag an **element** from the **XML Schema** tab of the Toolbox and do the following:

   - If you want to add an element to an existing element, complex type, or group: drop the **element** on its design grid.

     The element will appear as a design grid below the existing grid, showing the hierarchical (nested) relationship between them.

     - or -

   - If you want the new element to have global scope: drop the element on the design surface.

     A design grid appears.

3. In the grid header, select **element1** and type a new value for the name of the element. For more information, see the "Naming Elements and Attributes" section of XML Elements, Attributes, and Types.
4. In the cell to the right of the element name choose a data type from the drop-down list.
5. In the Properties window set the desired properties for your element, such as **minOccurs**, **maxOccurs**. For more information, see element.

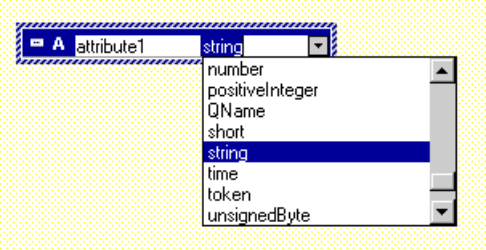
Creating Attributes in XML Schemas

Attributes are like properties of an element. When you declare an attribute, you name it and associate the name with a simple data type. Attribute declarations are defined as simple types. For more information, see XML Elements, Attributes, and Types.

Attributes can be added to the following:

- Schema
- Elements
- AttributeGroups
- ComplexTypes

Visual representation of an attribute in the XML Designer



To create an attribute with the XML Designer

1. Add an **XML Schema** or **Dataset** to your project. For more information, see Adding New Schemas.
2. In Schema view, drag an **attribute** from the **XML Schema** tab of the Toolbox to the XML Designer.

   - If you want to create an attribute with global scope within the schema: drop the attribute on the design surface.

     A design grid appears.

     - or -

   - If you want to add an attribute to an existing element, attributeGroup, or complexType, drop the attribute on the element.

     The attribute appears as a row within the design grid.

3. In the design grid, select **attribute1** and type a new value for the name of the attribute. For more information, see the "Naming Elements and Attributes" section of XML Elements, Attributes, and Types.
4. In the cell to the right of the attribute name, choose a data type from the drop-down list.

User-Defined Simple Types in XML Schemas

User-defined simple types are restrictions put on the content of elements or attributes. A user-defined simple type will always restrict the contents of an element to a subset of the existing simple type it was derived from. For example, `string` is a simple type. You can apply the `length` facet with a value of 2 to restrict data content to a two-character string. The existing simple type can be either one of the built-in types or a user-defined simple type already declared in your XML Schema.

If an element only needs to be a subset of an existing built-in data type, then a user-defined simple type should be used. Additionally, if this type of element definition is only needed once in your schema, an unnamed simple type should be used. If you need several occurrences of the same type, use a named simple type.

Simple types are defined using the **simpleType** element and cannot contain subelements or attributes. There are over 40 simple types built into the XML Schema definition of the World Wide Web Consortium (W3C). For more information, see Primitive XML Data Types.

Restricting an existing simple type is accomplished by applying facets. Facets define a set of legal values for a simple type. For more information, see Data Type Facets.

The following example shows how to define your own simple type and apply the `maxInclusive` facet to it.

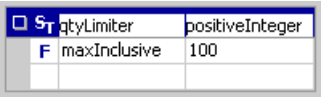
The following defines an element named `quantity` that is of the simple built-in type **positiveInteger**:

```
<xs:element name="quantity" type="xs:positiveInteger" />
```

In order to conform to the above declaration, the valid values of the `quantity` element would be limited to any positive integer. If you needed to limit the `quantity` element to a value less than 101, you would create a user-defined simple type. The following example shows how to create a simple type named `qtyLimiter` and apply the **maxInclusive** facet with a value of 100.

```
<xs:simpleType name="qtyLimiter">
   <xs:restriction base="xs:positiveInteger">
      <xs:maxInclusive value="100" />
   </xs:restriction>
</xs:simpleType>
```

This is how the previous code is represented visually in the XML Designer:



This user-defined simple type can now be applied to element declarations within the same XML Schema (.xsd file). The following example shows how to declare a `quantity` element with the **qtyLimiter** type.

```
<xs:element name="quantity" type="qtyLimiter" />
```

If there were elements other than `quantity` that had the same content requirements, they could be declared with the user-defined **qtyLimiter** type as well.

Creating Simple XML Types

You can define simple types in your XML Schema. Simple types allow you to create new types by adding restrictions (such as limiting the length of a data entry) to existing types. For example, you could create a stateCode simple type that is limited to two characters. These new types can then be applied to elements and attributes.

You restrict the contents of a simple type by applying facets to the type. Facets set limits on the type of content a simple type can contain.

> **Tip** If you need to define an element that contains subelements or attributes, create a complex type. For details, see Creating Complex XML Types.

To create a new simple type

1. Add an **XML Schema** or **DataSet** to your project. For details, see Adding New Schemas.
2. Drag a **simpleType** object from the **XML Schema** tab of the **Toolbox** to the design surface.

   A grid appears in the designer.
3. In the edit box in the grid header, select **simpleType1** and type a new value to rename the object.
4. In the drop-down list box in the grid header, select the appropriate data type.
5. If you want to add restrictions, set the facets you want to use, following these steps:
   a. In the first blank row of the grid, click in the first cell and choose the facet you want to set from the drop-down list box.
   b. In the second cell for that same row, specify the appropriate value. For details, see Data Type Facets.

You can now use this type in defining new elements and complex types.

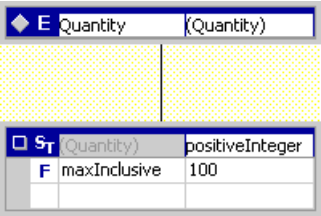
Creating Unnamed Simple Types

An unnamed type is a data type that is nested (in-line) within the definition of an element. Use an unnamed type when a type is only needed once within your schema.

Unnamed simple types are constructed of built-in types and contain only facets to restrict their contents. For more information, see User-Defined Simple Types in XML Schemas.

Visual representation of an unnamed simple type in the XML Designer



To create an element or attribute defined as an unnamed simpleType

1. Add an **XML Schema** or **Dataset** item to your project. For more information, see Adding New Schemas.
2. Drag an **element** or **attribute** from the **XML Schema** tab of the Toolbox to the design surface. For more information about whether to use an element or attribute, see the "Should I use an Element or an Attribute?" section of XML Elements, Attributes, and Types.

   A design grid appears in the designer.

3. In the grid header, select the default name (element1 or attribute1) and type a new name for the element or attribute.
4. In the drop-down list box in the grid header, select **Unnamed simpleType**.

   A simpleType design grid appears below the original grid, which represents that it has a child relationship.

5. In the simpleType design grid, select a data type in the drop-down list to the right of the disabled name box.

   This will be the base data type that this simple type will be derived from.

6. In the first blank row of the grid, click the cell below the disabled name box and choose a facet from the drop-down list. For more information, see Data Type Facets.

simpleType Element | XML Schemas and the XML Designer | XML Elements, Attributes, and Types | Named vs. Unnamed Types and Groups | User-Defined Simple Types in XML Schemas | Complex Types in XML Schemas | Creating XML Schemas and Datasets | Relational Data in XML Schemas | XML Files

Complex Types in XML Schemas

Complex types are user defined data types that can include other elements or attributes. Complex types can contain elements defined as either simple or complex. Complex types can also include attributes and groups, whereas simple types can only contain facets.

Complex types are defined using the **complexType** element and typically contain combinations of element, attribute, and group declarations, as well as references to globally declared elements and groups. A complex type can be thought of as a mini-schema that defines the valid structure and data contained within a specific element.

Although complex types can be either named or unnamed, the following examples demonstrate named complex types. For more information about unnamed types, see Named vs. Unnamed Types and Groups.

Typical Use of a Complex Type

A common scenario where a complex type would be used is as part of a schema that validates a purchase order by requiring a shipping address and a billing address. You would define a complex type that represents an address and declare shipTo and billTo elements of that complex type.

The following example shows how to create a complex type named `usAddress`:

```
<xs:complexType name="usAddress">
   <xs:sequence>
      <xs:element name="name" type="xs:string" />
      <xs:element name="street" type="xs:string" />
      <xs:element name="city" type="xs:string" />
      <xs:element name="state" type="xs:string" />
      <xs:element name="zip" type="xs:string" />
   </xs:sequence>
</xs:complexType>
```

An element declared with the `usAddress` type would look like this:

```
<xs:element name="ShipTo" type="usAddress" />
```

The following example shows how to declare multiple elements using your defined complex type:

```
<xs:element name="customerInfo">
  <xs:complexType>
     <xs:sequence>
        <xs:element name="Name" type="xs:string" />
        <xs:element name="ShipTo" type="usAddress" />
        <xs:element name="BillTo" type="usAddress" />
     </xs:sequence>
  </xs:complexType>
</xs:element>
```

This is a visual representation of the preceding code in the XML Designer. Notice the globally declared complex type named `usAddress` at the bottom, and how the `ShipTo` and `BillTo` elements are defined with the `usAddress` type in the `customerInfo` element at the top.

Walkthrough: Creating an XML Schema with the XML Designer | World Wide Web Consortium (http://www.w3.org/) | XML Schemas and the XML Designer | XML Elements, Attributes, and Types | Named vs. Unnamed Types and Groups | User-Defined Simple Types in XML Schemas | Creating XML Schemas and Datasets | Relational Data in XML Schemas | XML Files

Creating Complex XML Types

Complex types allow you define elements with attributes or subelements in your XML Schema. For example, you could define an addressType made up of name, address, and postal code. This new type could then be used by an Address element.

To create a new complexType object

1. Add an **XML Schema** or **DataSet** to your project. For details, see Adding New Schemas.
2. Drag a **complexType** object from the **XML Schema** tab of the **Toolbox** onto the design surface.
3. In the edit box in the grid header, select **complexType1** and type a new value to rename the object.
4. To specify the elements for the complex type, follow these steps:
   a. In the first empty row in the grid, select the small cell next to the asterisk to access the element type drop-down list box.
   b. Choose the type of element from the list.
   c. In the second cell, replace the default name with a name for the element you chose.
   d. In the third cell, select the type for the element. You can choose an existing type, an unnamed type, or a type you have created.
5. Continue adding elements to the complex type until it is fully declared.

To delete an element from a complexType

- Right-click the row you want to delete, and then click **Delete** on the shortcut menu.

To delete an entire complexType

- Right-click the header of the grid, and then click **Delete**.

Creating XML Schemas: High-Level Process | Complex Types in XML Schemas|
Walkthrough: Creating an XML Schema with the XML Designer | complexType Element

Creating Unnamed Complex Types

An unnamed complex type is a user defined type definition that is constructed in-line as part of the content model definition (as opposed to a global declaration being named and explicitly referenced). Unnamed types are typically used when a particular content model is needed to describe a single occurrence of an element. If you need to reuse a type definition then you should create a named type. For more information, see Named vs. Unnamed Types and Groups.

Unnamed complex types can be created with the XML Designer by adding elements and attributes to the design grid of an existing element.

To gain an understanding of where unnamed complex types fit into the overall process of creating an XML Schema, see Creating XML Schemas: High-Level Process for a summary of the steps and Walkthrough: Creating an XML Schema with the XML Designer for step-by-step instructions for a representative scenario: creating a purchase-order schema.

To create a new unnamed complexType

1. Add an **XML Schema** or **Dataset** item to your project. For more information, see Adding New Schemas.
2. Drag an **element** from the **XML Schema** tab of the Toolbox onto the design surface.

   > **Note** An unnamed type is defined inline as part of an element declaration. On the design surface, you create an unnamed complex type by building up the content model in the design grid of an element.

3. In the grid header, select **element1** and type in a new name for the element.
4. Choose **unnamed complex type** from the list in the grid header.
5. To define the content of an unnamed complex types, follow these steps:
   a. In the first empty row in the grid, select the small cell next to the asterisk to access the element type drop-down.
   b. Choose the type of element from the list.
   c. Use the TAB key to navigate to the next cell and replace the default name with a new name for this element.
   d. In the third cell, select the type for the element. You can choose an existing type, an unnamed type, or an existing user-defined type.

      > **Note** If you choose an unnamed type, a child element will appear on the design surface. Follow the procedure in step 5 to define that type as well.

6. Repeat Step 5 until the type is fully defined.

Walkthrough: Creating an XML Schema with the XML Designer | complexType Element | XML Schemas and the XML Designer | XML Elements, Attributes, and Types | Named vs. Unnamed Types and Groups | User-Defined Simple Types in XML Schemas | Complex Types in XML Schemas | Relational Data in XML Schemas | XML Files

Element Groups

Groups of elements can be defined in order to control how the individual elements within a group occur in XML data. For more information, see Creating Element Groups in XML Schemas.

You use element groups when you want to impose the following occurrence constraints on a group of elements:

Use the:	Occurrence Constraint:
sequence group	all elements occur in the exact order
choice group	only one element in the group occurs
all group	all elements occur or none at all

Groups can be named or unnamed. For more information, see Named vs. Unnamed Types and Groups.

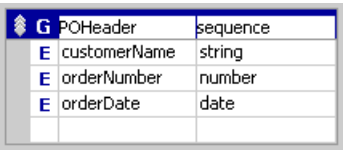
Sequence Group

Grouping with the sequence element declares that subelements must appear in the exact order as indicated. The following example shows how to define a group named `POHeader`. By declaring the group of subelements within the `<xs:sequence>` element, any XML data validated by this schema must contain the `customerName`, `orderNumber`, and `orderDate` elements in the exact order.

The following XML Schema code defines a **sequence group** named `POHeader`:

```
<xs:group name="POHeader">
   <xs:sequence>
      <xs:element name="customerName" type="xs:string" />
      <xs:element name="orderNumber" type="xs:number" />
      <xs:element name="orderDate" type="xs:date" />
   </xs:sequence>
</xs:group>
```

Visual representation of a sequence group named `POHeader` in the XML Designer



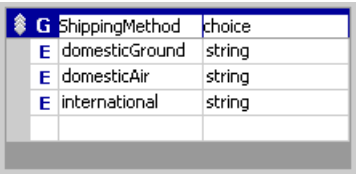
Choice Group

Grouping with the choice element declares that only one of the subelements can appear in XML data. The following example shows how to define a choice group named `ShippingMethod`. By declaring subelements within the `<xs:choice>` element, any XML data validated by this schema must contain only one shipping method.

Sample bit of XML Schema code defining a **choice group** named `ShippingMethod`:

```
<xs:group name="ShippingMethod">
   <xs:choice>
      <xs:element name="domesticGround" type="xs:string" />
      <xs:element name="domesticAir" type="xs:string" />
      <xs:element name="international" type="xs:string" />
   </xs:choice>
</xs:group>
```

Visual representation of a choice group named `ShippingMethod` in the XML Designer



All Group

Grouping with the **all** element declares that an instance document can contain all or none of the subelements, and they may appear in any order.

The following example declares a group named `PaymentInfo`. By declaring subelements within the `<xs:all>` element, any XML data validated by this schema can contain either all the elements, in any order, or none. (If no payment were made, there would not be any payment info at all).

Additionally the **All** group has the following specific rules governing its usage:

- The all group must be at the top level of any content model.
- The subelements must be individual elements (no groups).
- It must be the sole child at the top of the content model. This means that no subelements are allowed outside the group tag.
- No element in the content model may appear more than once. This is equivalent to setting the values of minOccurs=0 and maxOccurs=1.

The following XML Schema code defines an **all group** named `PaymentInfo`:

```
<xs:group name="PaymentInfo">
   <xs:all>
      <xs:element name="paymentDate" type="xs:date" />
      <xs:element name="paymentAmount" type="xs:integer" />
      <xs:element name="paymentOnAccount" type="xs:boolean" />
   </xs:all>
</xs:group>
```

Visual representation of an `all` group named PaymentInfo in the XML Designer

XML Schemas and the XML Designer| XML Elements, Attributes, and Types | Named vs. Unnamed Types and Groups | User-Defined Simple Types in XML Schemas | Complex Types in XML Schemas | Creating XML Schemas and Datasets | Relational Data in XML Schemas | XML Files

Creating Element Groups in XML Schemas

Elements can be constructed into groups in order to control the sequence and occurrence behavior of the elements within the group. For more information, see Element Groups.

Create a group when you need to have:

- All elements occur in the exact order (sequence group).
- Only one element in the group occur (choice group).
- All elements occur, or none at all (all group).

Additionally, groups can be either named or unnamed. You should have a good understanding of the difference between named and unnamed definitions before creating a group. For more information, see Named vs. Unnamed Types and Groups.

For an overview of where element groups fit into the process of creating an XML Schema, see Creating XML Schemas: High-Level Process for a summary of the steps and Walkthrough: Creating an XML Schema with the XML Designer for step-by-step instructions for a representative scenario: creating a purchase-order schema.

Creating Named Groups

Named groups are declared globally and explicitly named. This provides the means for reusing the group in multiple complex type definitions.

To create a named group with the XML Designer

1. Add an **XML Schema** or **Dataset** to your project. For more information, see Adding New Schemas.
2. Drag a **group** from the **XML Schema** tab of the Toolbox to the design surface.

   A design grid appears.

3. In the grid header, select **group1** and type a new name for the group.
4. In the cell to right of the group name, do one of the following:

   - If you want all elements occur in the exact order, select **sequence.**

     - or -

   - If you want only one element in the group occur, select **choice**.

     - or -

   - If you want all or none of the elements occur, select **all**.

5. To define the contents of the group, follow these steps:
   a. In the first empty row in the grid, select the small cell to the right of the asterisk to access the drop-down list.
   b. Use the TAB key to navigate to the next cell and replace the default name with a new name for this element.
   c. In the third cell, select the data type for the element.
6. Continue adding elements to the group until it is fully defined.

Creating Unnamed Groups

An unnamed group is defined as an inclusive part of the content model of a complex type definition, as opposed to being named and explicitly referenced. For more information, see Named vs. Unnamed Types and Groups.

Unnamed sequence groups are actually created by default with complex type definitions. If you drag an element onto the design surface and switch to XML view, you will see the `<sequence />` element within the content model. You just created an unnamed sequence group.

The actual grouping option is defined by setting the **Order** property as defined in step 8 below.

To create an unnamed group with the XML Designer

1. Drag an **element** from the Toolbox onto the design surface.

   A design grid appears.

2. In the grid header, select **element1** and type in a new name for the element.
3. To define the contents of the group, follow these steps:
    a. In the first empty row in the grid, select the small cell to the right of the asterisk to access the drop-down list.
    b. Choose the type of element from the list. For more information, see XML Schema Elements.
    c. Use the TAB key to navigate to the next cell and replace the default name with a new name for this element.
    d. In the third cell, select a data type for the element.
4. Continue adding elements to the group until it is fully defined.
5. In the Properties window, access the drop-down list and select the element you just created.
6. Expand the **complexType** section.
7. Locate the **Order** property.
8. Set the property to the desired group type.

    - If you want all elements to occur in the exact order, set the **Order** property to **sequence**.

      - or -

    - If you want only one element in the group to occur, set the **Order** property to **choice**.

      - or -

    - If you want all or none of the elements to occur, set the **Order** property to **all**.

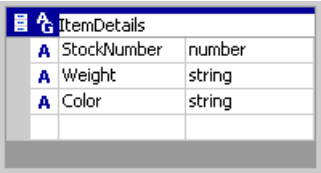
Attribute Groups

Attributes can be arranged into a named group that can be included as part of a complex type definition. Attribute groups are defined and named in one place so that they can be reused and easily updated.

The following example shows how to define an attribute group named `ItemDetails` that is comprised of three attributes: `StockNumber`, `Weight`, and `Color`.

Visual representation of an attribute group named `ItemDetails` in the XML Designer



The following example shows the XML code that represents the attribute group illustrated above:

```
<xs:attributeGroup name="ItemDetails">
      <xs:attribute name="StockNumber" type="xs:number" />
      <xs:attribute name="Weight" type="xs:string" />
      <xs:attribute name="Color" type="xs:string" />
</xs:attributeGroup>
```

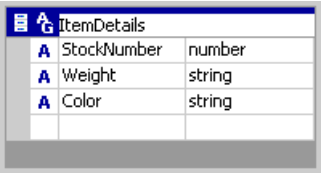
attributeGroup | XML Schemas and the XML Designer | XML Elements, Attributes, and Types | Creating XML Schemas and Datasets | Relational Data in XML Schemas | XML Files

Creating Attribute Groups in XML Schemas

An attribute group allows you to reuse the same set of attributes within your schema. For more information, see Attribute Groups.

To gain an understanding of where creating attribute groups fits into the overall process of creating an XML Schema, see Creating XML Schemas: High-Level Process for a summary of the steps and Walkthrough: Creating an XML Schema with the XML Designer for step-by-step instructions for a representative scenario: creating a purchase-order schema.

Visual representation of an attribute group in the XML Designer



To define an attributeGroup with the XML Designer

1. Add an **XML Schema** or **Dataset** to your project. For more information, see Adding New Schemas.
2. In **Schema** View, drag an **attributeGroup** from the **XML Schema** tab of the Toolbox to the design surface.

   A design grid appears.

3. In the grid header, select **attributeGroup1** and type a new value for the name of the **attributeGroup**.
4. In the next empty row in the grid, select the small cell next to the asterisk and choose the desired attribute type to include in the attribute group from the drop-down list:

   - If you want to include any attribute from the specified namespace in this attribute group, choose **anyAttribute**.
   - If you want to include a standard attribute in this attribute group definition, choose **attribute**.
   - If you want to include some other attribute group in this attribute group definition, choose **attributeGroup**.

5. Use the following table to complete the attribute definition in the design grid based on your selection in step 4:

Attribute Type (step 4)	**Name field**	**Type field**
anyAttribute	No input	No input
attribute	Type a name for the attribute	Select a type from the drop-down box
attributeGroup	Type 'ref=*x*' where *x* is the name of a top level attribute group you want to include	No input

6. Repeat steps 4 and 5 until your attribute group is fully defined.

Keyboard Shortcuts for the XML Designer

The following tables list the keyboard shortcuts that can be used for navigation while working with the XML Designer:

Navigating the Environment

Action	Shortcut
Move focus to the Toolbox	CTRL+ALT+X
Move focus to the design surface	ALT+W, then select the number corresponding to the window you want
Move focus to Solution Explorer	CTRL+ALT+L
Move focus to the Properties Window	F4
Move focus to the Menu bar	ALT
Move focus to Server Explorer	CTRL+ALT+S

Navigating in Schema View

To select a specific grid in **Schema** view, press **F4** to navigate to the Properties window. Press TAB until the main drop-down list is selected. Arrow to the desired object and press ENTER.

Action	Shortcut
Move from grid to grid	TAB
Move from grid to grid	Arrow keys
Place selected grid into edit mode	ENTER
Move selected grid in the direction of the ARROW key pressed	CTRL+Arrow keys
Toggles between **XML Source** and **Schema** view	CTRL+PAGEDOWN

Navigating within an Element Grid in Schema View

Action	Shortcut
Move forward from cell to cell (including header row)	TAB
Move from cell to cell (excluding the header row) if cells are empty	Arrow keys
Expand the drop-down list in cells that have them	ALT+Arrow key
Exit edit mode and return to navigating the designer	ESC

Navigating the Toolbox

Action	Shortcut
Move up through the list of items	UP ARROW
Move down through the list of items	DOWN ARROW
Cycle through the list of items	TAB

Creating XML Schemas and Datasets

ADO.NET typed datasets are classes that are generated from XML Schemas (.xsd file). As changes are made to the schema file the definition of the dataset class changes as well. When working with XML Schemas and typed dataset representations in Visual Studio at design time there is essentially no difference. They are both .xsd files in the XML Designer, the difference being that typed datasets have an associated class file and a predefined document (or root) node that represents the encompassing dataset.

A schema serves these functions:

- It describes the "shape" of the XML document — for example, whether the XML document is constructed hierarchically or in a keyed relationship.
- It validates data being imported from an XML stream or document into a dataset.
- It establishes the relational structure of the dataset's tables and columns, the key columns, constraints, relationships between tables, and so on; the information is used when generating a DataSet Class. In this respect, the schema serves a special role that requires it to support dataset-specific features.

For more information, see Introduction to Datasets.

Relationship Between XML Schemas and Datasets

A typed ADO.NET dataset is a class with an associated XML Schema, as opposed to an untyped dataset that is not a class and has no associated schema. The typed dataset class is derived from a dataset class, which inherits all of the methods, events and properties of a dataset. Additionally, a typed dataset provides strongly typed methods, events, and properties meaning you can access tables and columns by name, instead of iterating through collections. A typed dataset also incorporates table and column names into the statement completion feature of Visual Studio. This facilitates code that is both easier to write as well as read. Additionally, with a typed dataset, type mismatch errors are caught when the code is compiled rather than at run-time.

When a typed dataset is generated at design time, a dataset class and an associated XML Schema is created in your project. XML Schemas define and validate the data being imported from XML streams or documents into typed datasets. The XML Schema associated with the dataset can be loading into the XML Designer providing a visual representation of the dataset structure that can be edited and viewed.

> **Note** An untyped ADO.NET dataset is a dataset that does not have an associated XML Schema. Additionally, at design time, datasets do not contain any data. Since an untyped dataset contains no data or structure, XML Schemas cannot be generated from untyped datasets at design time. During run time, once the dataset has been populated with data, an XML Schema based on that data could be generated programmatically.

XML Schemas in Visual Studio conform to the specification for schemas published by the World Wide Web Consortium (W3C). Schema elements, whether created to validate XML documents or to define associated dataset classes, are all defined in accordance with the W3C schema specification. In situations where schema syntax is not sufficient to describe certain features of ADO.NET datasets, custom attributes are used to define ADO.NET specific characteristics. While viewing a schema in XML view these custom attributes can be identified with the msdata: qualifier. However, it is important to note that the W3C spec permits custom attributes, which will be ignored by applications that do not process ADO.NET datasets.

Creating XML Schemas: High-Level Process

There are several steps involved in creating an XML Schema (.xsd file) from scratch. First, you must examine the data needs of your organization and map out the structure of your data to determine the types, elements, and relationships you will need in the schema. After you have planned your schema out, you can quickly create it using the XML Designer. For an example of how to create a schema, see Walkthrough: Creating an XML Schema with the XML Designer.

> **Note** In addition to creating a schema from scratch, you can infer schemas from existing XML documents (.xml files), and then edit them as needed in the XML Designer. For more information, see Creating XML Schemas from XML Files.

To create an XML Schema

1. Determine the design needed for your schema.
2. Add a schema to your project. For more information, see Adding New Schemas.
3. Define the types that will be used in your schema. For more information, see any of the following topics:

For instructions on	See
Creating a simple named type	Creating Simple XML Types
Creating a complex named type	Creating Complex XML Types
Creating a simple unnamed type	Creating Unnamed Simple Types
Creating a complex unnamed type	Creating Unnamed Complex Types

4. Add the appropriate elements to the schema, making use of the types you have defined.

For instructions on	See
Creating an element definition	Creating Elements in XML Schemas
Creating an attribute definition	Creating Attributes in XML Schemas
Grouping sets of elements	Creating Element Groups in XML Schemas

See Also

Adding New Schemas | Creating Simple XML Types | Creating Complex XML Types | Creating Unnamed Simple Types | Creating Unnamed Complex Types | Creating Elements in XML Schemas | Creating Attributes in XML Schemas | Creating Element Groups in XML Schemas

Adding New Schemas

XML Schemas are used to ensure consistency among XML documents (.xml files) by describing the structure of data. To create new XML Schemas in the XML Designer, start by adding a dataset or schema to your project, depending on your needs:

- If you add a DataSet item from the Add New Item dialog box, the output will be both a schema (an .xsd file) and an automatically generated dataset.
- If you add an XML Schema item, the output will be only a schema file. You can manually generate a dataset from the schema.

For details about the relationship between XML Schemas and datasets, see Introduction to Data Access with ADO.NET.

To add a new schema to the project

1. From the **Project** menu, choose **Add New Item**.
2. Do one of the following:

    - To add a schema, access the appropriate folder and double-click **XML Schema.**

      An XML Schema file (.xsd file) is added to your project.

    - To add a dataset, access the appropriate folder and double-click **DataSet**.

      An XML Schema file and typed **DataSet** class file (.vb or .cs file) are added to your project.

      Note You may have to click the **Show All Files** button in Solution Explorer to see the files that have been generated.

3. To create the schema, add elements and attributes. For details, see Creating XML Schemas: High-Level Process.

Walkthrough: Creating an XML Schema with the XML Designer | Introduction to XML Schemas| Relational Data in XML Schemas | Creating ADO.NET Typed DataSets from Schemas

Creating XML Schemas and Datasets from Existing Data

The XML Designer allows you to easily create schemas and datasets based on any table, stored procedure, or view that can be browsed in the data connection area of Server Explorer. Additionally, you can pick and choose individual columns if the entire data structure is not needed.

You create a schema based on existing data sources when the existing source contains the desired structure for your application. This is a quick way to build up your schema without having to define each individual element.

Schemas and datasets can also be created programmatically from any data source that you have access to at run time.

To create a schema to match an existing data source

1. In Solution Explorer, right-click the project you want to add the dataset to, select **Add**, and then select **Add New Item**.
2. In the **Add New Item** dialog box, select **Dataset**, give the dataset a name, and then click **Open**.

   A new, blank schema file (.xsd) and a corresponding **Dataset** class file are added to your project.

   > **Note** The name you use will also be the name of the **Dataset** class file generated from the schema.

3. In Server Explorer, expand the **Data Connections** node and then expand the node for the connection to the data source you want to use.

   > **Note** If you do not already have a connection, create one. For more information, see Adding New Data Connections in Server Explorer.

4. In the **Connection** node, expand the node for **Tables**, **Stored Procedures**, or **Views**, depending on what you want to infer the schema structure from.
5. If you want to build the schema based on only specific columns (not on all columns in the data source), open the source node and select the columns you want.
6. Drag the selected table, view, stored procedure, or columns onto the XML Designer.
7. Save the schema.

   Visual Studio creates the schema structure from the elements you specify and regenerates the corresponding class file for your typed dataset.

8. If you have added multiple tables to the dataset and want to establish a relationship between them, add a **DataRelation** object to the schema. For more information, see Creating DataRelation Objects with the XML Designer.

If you need to make changes to the schema, you can use the XML Designer to add, edit, and remove elements.

Creating New Typed Datasets with the XML Designer

A typed dataset is a class with an associated XML Schema. If your application needs a typed dataset and there is no available data source to base your associated schema on, you can create a typed dataset schema manually using the XML Designer. If there is a data source that has the structure you want for your dataset, see Creating XML Schemas and Datasets from Existing Data.

To create a schema manually using the XML Designer

1. In Solution Explorer, right-click the project you want to add the dataset to, select **Add**, and then select **Add New Item**.
2. In the **Add New Item** dialog box, select **Dataset**, give the dataset a name, and then click **Open**.

   Visual Studio adds a new, blank schema file (.xsd) to the project as well as a corresponding **Dataset** class file.

   > **Note** The name you use will also be the name of the **Dataset** class file generated from the schema.

3. To add a table definition to the schema, drag an **element** object from the **XML Schema** tab of the Toolbox onto the designer.
4. Name the table by overwriting **element1** in the box at the top of the element.

   This will change the type of the element to match what typed in.

5. To add a column definition to the table, move to a blank line in the table definition and select either **element** or **attribute** from the type drop-down.
6. Assign a name and a data type to the new column definition.

   > **Note** When you create a column definition in a schema, you can create it as either an element or an attribute. The choice you make depends primarily on your own application requirements. If you are defining the schema to match a specification for sharing data with another application, then the specification will dictate your choice. If your dataset requires data types that are not built in to the W3C spec then you should define your columns as elements because elements are not restricted to the built in types, whereas attributes are.

7. To add a primary key definition to the table, drag a **key** element from the **XML Schema** tab of the Toolbox onto the table definition,
8. In the **Key Editor** dialog box:
   a. If the default name is not appropriate, type in a new name.
   b. In the **Fields** list, select the next empty line and use the drop-down list to choose the column to serve as the primary key.
   c. If there are multiple parts to the primary key, choose each part of the primary key separately, one per line.
   d. Check **Primary Key**.

   The option to allow null keys is disabled.

   > **Tip** To delete a key element, select the row with the key to be deleted, right-click it and choose **Delete Key**.

9. Repeat Steps 3 through 8 for each table you want to add to the dataset.
10. Save the schema.

    The corresponding class file is regenerated to incorporate the changes made.

Creating ADO.NET Typed DataSets from Schemas

The XML Designer can generate an ADO.NET typed dataset from an XML Schema (.xsd file).

To create an ADO.NET typed dataset from an existing schema

1. From the **Project** menu, choose **Add Existing Item.**
2. In the **Add Existing Item** dialog box, navigate to the schema you want to add, select the file, and click **Open**.
3. In Solution Explorer double-click the .xsd file you added to the project in the previous step.
4. From the **Schema** menu, choose **Generate DataSet**.

   A typed dataset has now been created and placed below the XML Schema file in Solution Explorer.

   > **Note** You may have to click the **Show All Files** button in Solution Explorer to see the files that have been generated.

Creating XML Schemas and Datasets from Existing Data | Creating XML Schemas from XML Files

Importing External Elements into XML Schemas

Elements from external namespaces can be imported and declared within your schema. Elements imported from multiple namespaces can be used in a schema. The only restriction is that the elements must be globally declared within the external schema.

Importing from other schemas enables types from different target namespaces to be used together.

To import existing data types into XML Schemas

1. Load an XML Schema into the XML Designer.
2. Place focus onto the design surface in **Schema** view.
3. Click **import** in the Properties window.
4. Open the import collection by clicking the ellipses next to the word **(Collection)**.

   The XmlImport Collection Editor appears.

5. Click **Add** to add an import reference to the collection.
6. The **id** field can be assigned any id.
7. The **namespace** field can be assigned any Uniform Resource Identifier (URI).
8. The **schemaLocation** field can be assigned any URI.

For more information about the **Collection Editor Dialog Box**, see Collection Editor Dialog Box.

Creating XML Schemas and Datasets | Relationship Between XML Schemas and Datasets | Relational Data in XML Schemas | XML Files | XML Namespaces | XML Schemas and Data

XML Namespaces

XML namespaces provide a method for uniqueness, which differentiates between multiple schema authors who use the same element names. Namespaces qualify the names of XML elements and XML attributes in XML document instances. A qualified name consists of a prefix and a local name, separated by a colon. The prefix functions only as a placeholder; it is mapped to a Uniform Resource Identifier (URI) that specifies a namespace. The combination of the universally managed URI namespace and the local name produces a name that should be universally unique.

Namespaces in XML must conform to the World Wide Web Consortium (WC3) specification called *Namespaces in XML*. For more information, see the W3C spec on Namespaces on the W3C Web site (http://www.w3.org/).

By default in Visual Studio each of the elements in a schema has a prefix `xs:` which is associated with the XML Schema namespace through the declaration, `xmlns:xs="http://www.w3.org/2001/XMLSchema"`, that appears in the schema element. The prefix `xs:` is used by convention to denote the XML Schema namespace, although any prefix can be used. The same prefix, and hence the same association, also appears on the names of built-in simple types — for example, `xs:string`. The purpose of the association is to identify the elements and simple types as belonging to the vocabulary of the XML Schema language rather than the vocabulary of the schema author.

See Also

XML Schemas and the XML Designer| XML Elements, Attributes, and Types | Changing the Target Namespace | Creating XML Schemas and Datasets | Relational Data in XML Schemas | XML Files

Changing the Target Namespace

When creating new XML Schemas, Visual Studio creates a default namespace entry within the opening schema tag. These entries need to be updated to reflect the proper namespace for your schema. The following example highlights the entries that need to be changed in a new XML Schema.

> **Note** New dataset schemas will have slightly different code than the following example, but you need only be concerned with the http://tempuri.org/ entries.

```
<?xml version="1.0" encoding="utf-8" ?>
<xs:schema id="XMLSchema1" targetNamespace="http://tempuri.org/XMLSchema1.xsd" elementFormDef
ault="qualified" xmlns="http://tempuri.org/XMLSchema1.xsd" xmlns:xs="http://www.w3.org/2001/X
MLSchema">
```

To change the target namespace in XML Schemas

1. Open your schema in XML view.
2. Locate the `targetNamespace="http://tempuri.org/..."` entry and replace it with the correct Uniform Resource Identifier (URI) for your schema.
3. Locate the `xmlns="http://tempuri.org/..."` entry and replace it with the correct URI for your schema.

XML Schemas and the XML Designer| XML Namespaces | Creating XML Schemas and Datasets | Relational Data in XML Schemas | XML Files

Walkthrough: Creating an XML Schema with the XML Designer

In this walkthrough you will create an XML purchase order schema as part of a Windows Application project. The walkthrough will consist of three main sections:

1. Creating a Windows Application project and adding an XML Schema.
2. Creating a relational table:
   a. Adding and defining a new **simpleType** object.
   b. Adding and defining a new **complexType** object.
   c. Adding and defining a new **Element** object.
3. Editing generated XML using the XML editor.

Creating a Windows Application and Adding an XML Schema

To create a new Windows Application project

1. From the **File** menu, point to **New**, and then click **Project** to display the **New Project** dialog box.
2. Depending on what language you want to use, select **Visual C# Projects** or **Visual Basic Projects** in the **Project Types** pane, and then select **Windows Application**.
3. Name the project **SampleSchema**.

To add an XML Schema to the project

- From the **Project** menu, choose **Add New Item**, then double-click the **XML Schema** icon in the **Add New Item** dialog box.

  The XML Designer appears.

Defining Simple and Complex Types

Before constructing the relational table, you will first build simple and complex type definitions that you will use to format specific elements of the purchase-order schema. The new types are built using existing XML data types, such as string and integer.

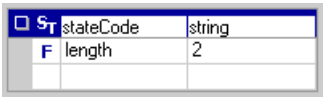
First you will define a simple type, which will be named **stateCode**. This simple type will be used to limit the size of a string to two characters.

To add an XML simpleType to the project

1. If not already open, double click the **XMLSchema1.xsd** file to bring up the XML Designer.
2. Click the **XML Schema** tab of the Toolbox and drag a **simpleType** onto the design surface.
3. Change the name of the simpleType by clicking the first text box in the header and replacing **simpleType1** with **stateCode**.
4. Set the base type for the stateCode type by clicking the drop-down list in the header and selecting **string**.
5. Navigate to the first cell in the next row by pressing the TAB key.
6. Select **facet** from the drop-down list.
7. Press TAB to go to the next cell and select **length** from the drop-down list.
8. TAB to the third cell of the same row, enter the value **2**.

   This requires that the value entered into the State field be two characters.

   Your stateCode should look like this in Schema view:

9. Click the **XML** tab at the bottom left of the **XML Designer** to see the XML that has been added:

```
<xs:simpleType name="stateCode">
   <xs:restriction base="xs:string">
      <xs:length value="2" />
   </xs:restriction>
</xs:simpleType>
```

This `stateCode` simple type will be used to define the `State` element within the complex type you will create in the next section.

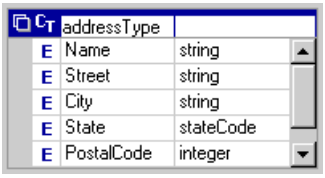
The complexType named `addressType` defines a set of elements that will appear in any element typed as addressType. For example, a `billTo` element will include information on names, addresses, and dates when its type is set to the previously defined addressType. By constructing the complex type and using it within an element, you are generating a nested relationship. For more information, see Creating Complex XML Types.

To add an XML complexType to the project

1. Click the **Schema** tab of the XML Designer.
2. Drag a **complexType** from the **XML Schema** tab of the Toolbox onto the design surface.
3. Change **complexType1** to **addressType** to name the type.
4. Add an XML attribute to addressType by clicking the first cell of the first row and selecting **element** from the drop-down list.
5. In the second column, change **element1** to **Name**.
6. In the third column, accept the default value of **string**.
7. Add the following XML elements and set their names and types as follows:

Element name	Data type
Street	string
City	string
State	stateCode
PostalCode	integer

   Your addressType should look like this in Schema view:



8. To see the XML that has been added to your .xsd file, click the XML tab at the bottom of the designer. You will see the following XML:

```
<xs:complexType name="addressType">
    <xs:sequence>
    <xs:element name="Name" type="xs:string"/>
    <xs:element name="Street" type="xs:string"/>
    <xs:element name="City" type="xs:string"/>
    <xs:element name="State" type="stateCode"/>
    <xs:element name="PostalCode" type="xs:integer"/>
    </xs:sequence>
</xs:complexType>
```

Creating a Relational Table

When you drag the element object from the Toolbox to the design surface, you are really adding an element containing an unnamed complexType. Including the unnamed complex type defines the element to be a relational table. Additional elements can then be added under the complexType to define the relation fields (or columns). If you define one of these new elements to be a new unnamed complexType, you are creating a nested relation inside of the parent relation with its own unique columns. For details see Tables, Columns, Keys, and Constraints in XML Schemas.

Defining new unnamed complex type elements within the PurchaseOrder or Items element creates additional nesting in the schema. Within one purchase order there can be many Items, and within each Item, many additional elements (such as price, size, and so on). In the following procedure, an element Items is added to the purchaseOrder relational table and typed as an unnamed complexType. Because you are defining a new relational table, this causes a new element to appear on the design surface. Within the new items relation, adding the item element and setting its type to unnamed complexType, creates another relational table, which also appears on the design surface.

To add an XML element to the project

1. Click the Toolbox and from the **XML Schema** tab drag an **element** object onto the design surface.

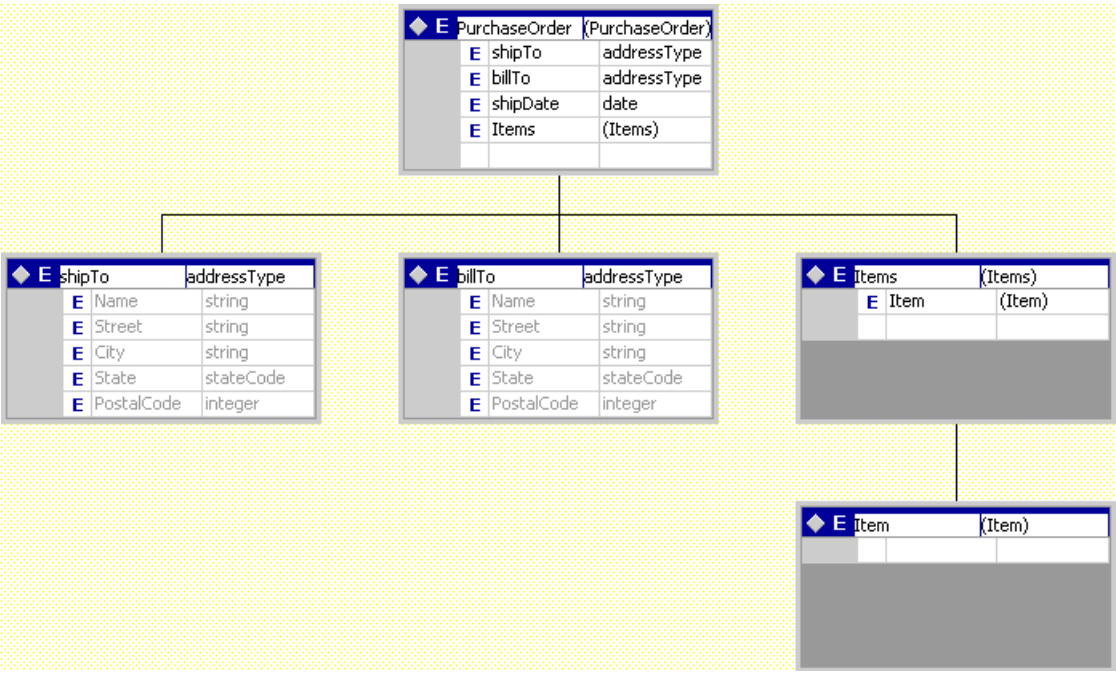
2. Change **element1** to **PurchaseOrder** to name the element. You can leave the data type as (**PurchaseOrder**).
3. Add an element to the purchase order by clicking the first cell of the first row and selecting **element** from the drop-down list.
4. Name the element **shipTo** and set its data type to **addressType**.
5. Add the following XML elements and set their names and types as follows:

Element name	Data type
billTo	addressType
shipDate	date
Items	unnamed complexType

When you type the Item element to be anonymous, an additional element is added to the design surface, which is another relational table.

6. In the **Items element**, add an element, name it **Item,** and set its type to **Unnamed ComplexType**.

Your purchase order should look like this in Schema view:



The following XML has now been added to your .xsd file:

```
<xs:element name="PurchaseOrder">
 <xs:complexType>
    <xs:sequence>
       <xs:element name="shipTo" type="addressType"/>
       <xs:element name="billTo" type="addressType"/>
       <xs:element name="shipDate" type="xs:date"/>
       <xs:element name="Items">
          <xs:complexType>
             <xs:sequence>
                <xs:element name="Item">
                   <xs:complexType>
                       <xs:sequence />
                   </xs:complexType>
                </xs:element>
             </xs:sequence>
          </xs:complexType>
       </xs:element>
     </xs:sequence>
  </xs:complexType>
</xs:element>
```

Editing XML

You can use the XML tab of the XML Designer to edit the XML that was generated when you added elements and types to the designer surface. The XML editor features IntelliSense and statement completion. An invalid statement is tagged with a red wavy line. Mousing over the incorrect statement causes an error message to appear.

To edit XML

1. Click the **XML** tab of the XML Designer to view the XML.
2. Within the `Item` element, change the self-closing tag (`<xs:sequence />`) into separate opening and closing tags (`<xs:sequence></xs:sequence>`).
3. After the `<xs:sequence>` tag in the `Item` element, type the following:

   ```
   <xs:element name="Quantity" type="xs:integer"/>
   <xs:element name="Price" type="xs:decimal"/>
   <xs:element name="ProductID" type="xs:integer"/>
   ```

   You have created three new elements — Quantity, Price, and ProductID — and defined data types for each.

4. Next type **<invalid/>** and note the red wavy line indicating an error. Mouse over the red wavy line to see an error message. Errors will appear in the Task List as well.
5. Delete the **<invalid/>** tag to fix the error.
6. Save the schema.

   The XML beneath the `Items` element should now look like the following in XML view:

   ```
   <xs:element name="Items">
     <xs:complexType>
       <xs:sequence>
         <xs:element name="Item">
           <xs:complexType>
             <xs:sequence>
               <xs:element name="Quantity" type="xs:integer"/>
               <xs:element name="Price" type="xs:decimal"/>
               <xs:element name="ProductID" type="xs:integer"/>
             </xs:sequence>
           </xs:complexType>
         </xs:element>
       </xs:sequence>
     </xs:complexType>
   </xs:element>
   ```

Introduction to XML Schemas | Relational Data in XML Schemas | Tables, Columns, Keys, and Constraints in XML Schemas | XML Elements, Attributes, and Types| XML Schema Reference (XSD)

Walkthrough: Reading XML Data into a Dataset

ADO.NET provides simple methods for working with XML data. In this walkthrough you will create a Windows application that will load XML data into a dataset. The dataset will then be displayed in a **DataGrid** control. Finally, an XML Schema based on the contents of the XML file will be displayed in a text box.

This walkthrough will consist of five main steps:

1. Create a new Visual Basic or Visual C# project.
2. Create an XML file to be read into the dataset.
3. Create the user interface.
4. Add code to create the dataset, read the XML file, and display it in a **DataGrid** control.
5. Add code to display the XML Schema based on the XML file in a **TextBox** control.

Create a New Project

In this step, you will create a Visual Basic or Visual C# project that will contain this walkthrough.

To create a new project

1. From the **File** menu, point to **New**, and then click **Project** to display the **New Project** dialog box.
2. Depending on what language you want to use, select **Visual Basic Projects** or **Visual C# Projects** in the **Project Types** pane, and then select **Windows Application**.
3. Name the project **ReadingXML**, then click **OK**.

   Visual Studio will add the **ReadingXML** project to Solution Explorer and display a new Windows Form in the designer.

Generate the XML File to Be Read into the Dataset

Because this walkthrough focuses on reading XML data into a dataset, the contents of an XML file is provided. This XML file must be located in a folder that will be accessible from the machine that you are using to create this application.

To create the XML file that will be read into the dataset

1. From the **File** menu, point to **New**, and then click **File**.

   The **New File** dialog box appears.

2. Select **XML File** and click **Open**.

   The XML file loads into the designer and is ready for edit.

3. Paste the following code into the editor below the XML declaration:

   Tip Right-click the editor and select **Paste as HTML**.

```

      <contract>true</contract>
    </authors>
  </Authors_Table>
```

4. From the **File** menu, point to **Save XMLFile1 As**.

   The **Save File As** dialog box appears.

5. Name the file **authors.xml** and click **Save**.

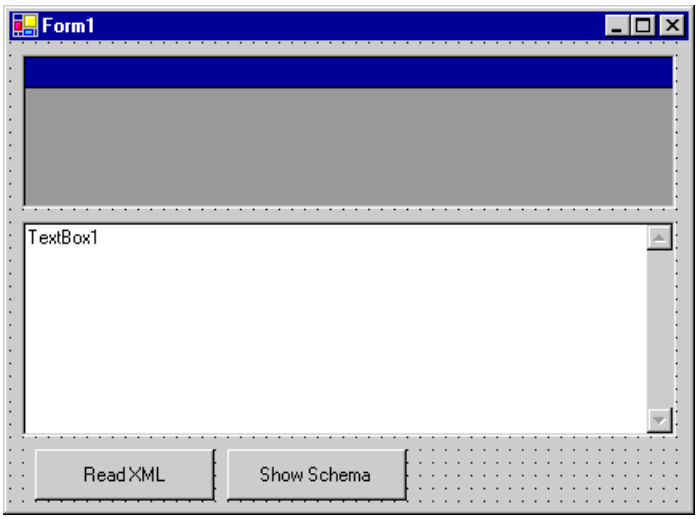
   Note Be sure to remember the complete path, it will be needed later in this walkthrough.

Create the User Interface

The user interface for this application will consist of the following:

- A **DataGrid** control that will display the contents of the XML file as data.
- A **TextBox** control that will display the XML Schema for the XML file.
- Two **Button** controls.
  - One button reads the XML file into the dataset and displays it in the **DataGrid** control.
  - A second button extracts the schema from the dataset, and through a StringWriter displays it in the **TextBox** control.

Initial layout for this application



To add controls to the form

1. From the **Windows Forms** tab of the Toolbox, drag the following controls onto the form:
   - 1 DataGrid control
   - 1 TextBox control
   - 2 Button controls
2. Set the following properties:

Control	Property	Setting
TextBox1	**Multiline**	**true**
	ScrollBars	**Vertical**
Button1	**Name**	**btnReadXML**
	Text	**Read XML**
Button2	**Name**	**btnShowSchema**
	Text	**Show Schema**

Create the Dataset that will Receive the XML Data

You will programmatically create a new dataset named **authors**. It will be declared at form level in order to be accessible from the **button_click** event handlers. For more information about datasets, see Introduction to Datasets.

To add the code to create a new dataset that will receive the XML data

1. With **Form1.vb** (VB users) or **Form1.cs** (C# users) selected in Solution Explorer, click the **View Code** button in the Solution Explorer toolbar.
2. In the declarations area, declare a new dataset named authors:

```
' Visual Basic
Dim dsAuthors As New DataSet("authors")

// C#
DataSet dsAuthors = new DataSet("authors");
```

Create the Event Handler to Read the XML into the Dataset

The **Read XML** button reads the XML file into the dataset and sets properties on the **DataGrid** that bind it to the dataset.

To add code to the btnReadXML_Click event handler

1. In Solution Explorer, select **Form1** and click the **View Designer** button on the Solution Explorer toolbar.
2. Double-click the **Read XML** button.

   The Code Editor opens at the **btnReadXML_Click** event handler.

3. Type the following code into the **btnReadXML_Click** event handler:

```
' Visual Basic
Dim filePath As String
filePath = "Complete path where you saved the XML file"
dsAuthors.ReadXml(filePath)
With DataGrid1
   .DataSource = dsAuthors
   .DataMember = "authors"
   .CaptionText = .DataMember
End With

// C#
string filePath = "Complete path where you saved the XML file";
dsAuthors.ReadXml(filePath);
dataGrid1.DataSource = dsAuthors;
dataGrid1.DataMember = "authors";
dataGrid1.CaptionText = dataGrid1.DataMember;
```

Create the Event Handler to Display the Schema in the Textbox

The Show Schema button creates a **StringWriter** object that is filled with the schema and displayed in the **TextBox**.

To add code to the btnShowSchema_Click event handler

1. In Solution Explorer, select **Form1.vb** and click the **View Designer** button.
2. Double-click the **Show Schema** button.

   The Code Editor opens at the **btnShowSchema_Click** event handler.

3. Type the following code into the **btnShowSchema_Click** event handler.

```
' Visual Basic
Dim swXML As New System.IO.StringWriter()
dsAuthors.WriteXmlSchema(swXML)
TextBox1.Text = swXML.ToString

// C#
System.IO.StringWriter swXML = new System.IO.StringWriter();
dsAuthors.WriteXmlSchema(swXML);
textBox1.Text = swXML.ToString();
```

Run the Application

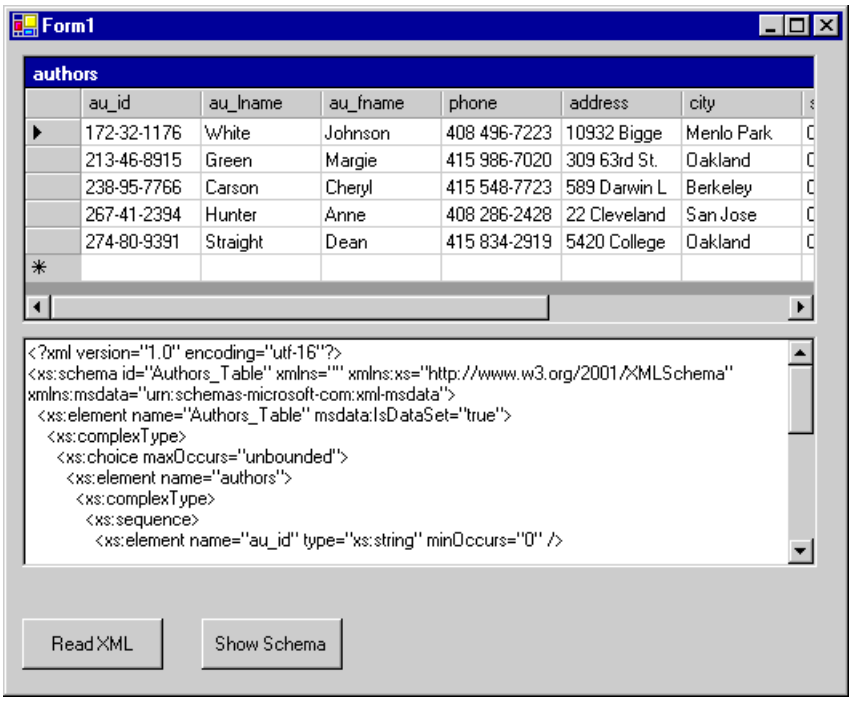
1. Press **F5** to run the application.
2. Click the **Read XML** button.

   The data grid displays the contents of the XML file.

3. Click the **Show Schema** button.

   The text box displays the XML Schema for the XML file.

Result of running the application



Next Steps

This walkthrough shows the basics of reading an XML file into a dataset, as well as creating a schema based on the contents of the XML file. Here are some tasks that might come next:

- Edit the data in the dataset and write it back out as XML. For more information, see DataSet.WriteXml Method.
- Edit the data in the dataset and write it out to a database. For more information, see Updating a Data Source with a Dataset.

Relational Data in XML Schemas

XML provides the following two approaches for representing relational data, and consequently, the schemas created to validate each construct are different as well.

- **One-to-many relationships** are represented as separate tables of rows that are related by common columns. These common columns are defined as keys within the tables, and a relationship is defined between them. The XML Designer provides the Edit Key and Edit Relation dialog boxes for creating keys and relationships respectively.
- **Nested relationships** are represented hierarchically by parent elements that contain nested child elements.

Tables, Columns, Keys, and Constraints in XML Schemas

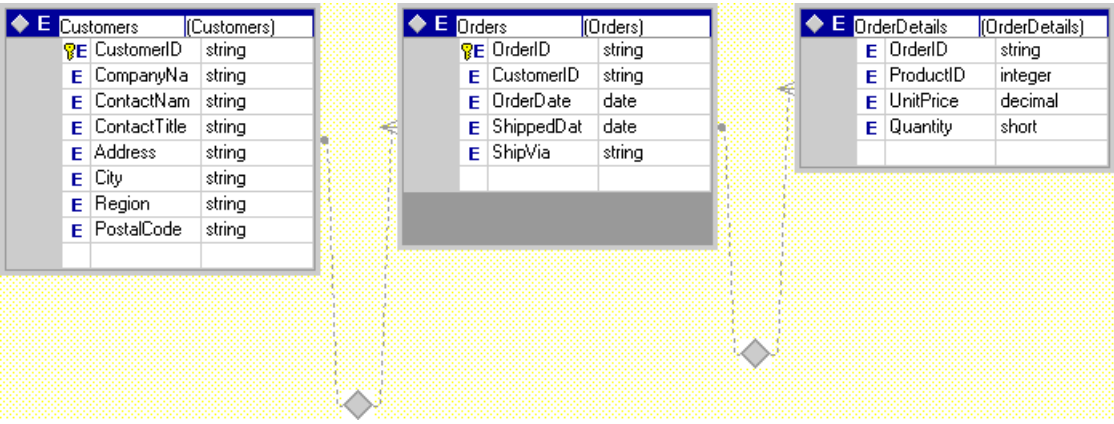
Relationships in XML Schemas involve creating individual tables with columns. If your schema uses a one-to-many relationship, then creating your XML Schema also involves designating the common columns as keys and keyrefs, creating relationships between them, and applying the appropriate constraints. Nested relationships in an XML Schema also involve creating tables with columns, except single column definitions may contain the complete definitions of related tables.

This topic will explain how typical database constructs such as tables, columns, primary keys, foreign keys, unique keys, and constraint rules are represented in XML Schemas and datasets.

Visual representation of relational data in the XML Designer



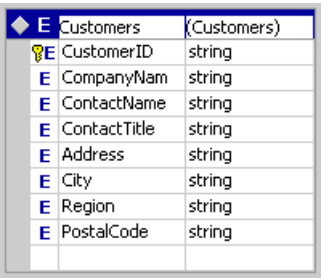
Tables

Tables in XML Schemas are represented by complex elements, and the columns are represented as sub-elements and attributes of that element. The name of the table is equal to the name of the element. The names of the columns are equal to the names of the sub-elements and attributes that make up the complex element. For more information, see Complex Types in XML Schemas.

For example, the following XML Schema could represent a table named `Customers`. The elements `CustomerID` through `PostalCode` represent the columns that make up the table. The `CustomerID` column is defined as the primary key.

> **Note** Notice how the primary key definition is hierarchically outside the
> Customers
> element definition, yet inside of a higher-level
> NewDataSet
> element. If there were other tables defined in this dataset, they would be nested within the
> NewDataSet
> element as well. This ensures that the primary key column is unique within the scope of the entire dataset (as opposed to being unique within the scope of just one record in the
> Customers
> table).

The following is a visual representation of the `Customers` table in the XML Designer:



The following example shows the XML code that represents the Customers table in a dataset named NewDataSet:

```
<xs:element name="NewDataSet" msdata:IsDataSet="true">
 <xs:complexType>
  <xs:choice maxOccurs="unbounded">
   <xs:element name="Customers">
    <xs:complexType>
     <xs:sequence>
```

```
        <xs:element name="CustomerID" type="xs:string"/>
        <xs:element name="CompanyName" type="xs:string"/>
        <xs:element name="ContactName" type="xs:string" minOccurs="0"/>
        <xs:element name="ContactTitle" type="xs:string" minOccurs="0"/>
        <xs:element name="Address" type="xs:string" minOccurs="0"/>
        <xs:element name="City" type="xs:string" minOccurs="0"/>
        <xs:element name="Region" type="xs:string" minOccurs="0"/>
        <xs:element name="PostalCode" type="xs:string" minOccurs="0"/>
       </xs:sequence>
      </xs:complexType>
     </xs:element>
    </xs:choice>
  </xs:complexType>
    <xs:unique name="NewDataSetKey1" msdata:PrimaryKey="true">
     <xs:selector xpath=".//Customers"/>
     <xs:field xpath="CustomerID"/>
    </xs:unique>
  </xs:element>
```

Columns

In the previous example, note how the individual columns (such as `CustomerID`, `CompanyName`, and `ContactName`) are declared as simple elements within a complex-type definition. The two elements without a **minOccurs** attribute are required columns, whereas the elements with the `minOccurs="0"` attribute are optional columns. The attribute `type="string"` refers to a simple type that is built-in to all XML Schemas. More importantly, note how the table is defined as an in-line unnamed complexType (the columns) within the `NameOfTable` element (the table). The following example shows how to define a table and its columns.

```
  <xs:element name="NameOfTable">
   <xs:complexType>
     <xs:sequence>
       <xs:element name="RequiredColumn" type="xs:string"/>
       <xs:element name="OptionalColumn" type="xs:string" minOccurs="0"/>
     </xs:sequence>
   </xs:complexType>
  </xs:element>
```

> **Note** When you create a column definition in a schema, you can create it as either an element or an attribute. The choice you make depends primarily on your own application requirements. If you are defining the schema to match a specification for sharing data with another application, then the specification will dictate your choice.

Primary Keys and Unique keys

Primary Keys

Primary keys ensure columns contain unique values that cannot be NULL. In the XML Designer, adding a key that does not have the **Primary key** option selected creates a unique key. Unique constraints ensure that columns do not contain duplicate values.

Based on the example earlier in this section, the following example shows how to define a `CustomerID` column as a primary key in an XML Schema:

```
  <xs:key name="NewDataSetKey1" msdata:PrimaryKey="true">
     <xs:selector xpath=".//Customers"/>
     <xs:field xpath="CustomerID"/>
```

```
</xs:key>
```

> **Note** By dragging a **key** from the **XML Schema** tab of the Toolbox onto an element and setting the appropriate fields, the previous code would be automatically generated by the XML Designer. For more information, see Creating Primary and Unique Keys in XML Schemas.

Unique Keys

Unique constraints can allow null values, whereas primary key constraints do not allow null values. Another consideration when deciding whether to use a primary or unique key is that tables can have multiple unique constraints but only one primary key.

Using the same example from earlier in this section, if you had an application that required that the `CompanyName` column must be unique, you would impose a unique key constraint on that column. The following example shows how to define a `CompanyName` column as a unique key in an XML Schema:

```
<xs:unique name="NewDataSetKey2">
   <xs:selector xpath=".//Customers" />
   <xs:field xpath="CompanyName" />
</xs:unique>
```

> **Note** By dragging a **key** from the **XML Schema** tab of the Toolbox onto an element and setting the appropriate fields, the previous code would be automatically generated by the XML Designer. For more information, see Creating Primary and Unique Keys in XML Schemas.

KeyRefs

A keyref defines the column on the many side of a one-to-many relationship, much like a foreign key in database terminology. An element that has been designated as a keyref has a relationship with the key or unique element in another table. Using the previous example, assume there is a table named `Orders` in the same dataset that has a column named `CustomerID`. You can create a **keyref** named `CustomerOrders` that creates the relationship between the `Customers` table and the `Orders` table.

```
<xs:keyref name="CustomerOrders" refer="NewDataSetKey1">
   <xs:selector xpath=".//Orders" />
   <xs:field xpath="CustomerID" />
</xs:keyref>
```

> **Note** By dragging a **Relation** from the **XML Schema** tab of the Toolbox onto an element and setting the appropriate fields, the previous code would be automatically generated by the XML Designer. For more information, see Creating DataRelation Objects with the XML Designer.

Referential Integrity

When creating a relationship with the Edit Relation dialog box, you can select the rules that affect what happens to related data. These rules are called *referential integrity*. When updating or deleting a record in a primary key column, there can be many records in another table that reference the primary key. The following table describes the different constraint rules that can be applied using the **Edit Relation** dialog box.

Rule	Description
Cascade	Deletes or updates related rows.
SetNull	Sets values in related rows to DBNull.
SetDefault	Sets values in related rows to DefaultValue.
None	No action taken on related rows.

Nested Relationships in XML

In the hierarchical representation of data that XML provides, nested relationships are represented by parent elements that contain nested child elements.

The following example shows `Orders` for a customer nested within a `Customers` element. In other words, the data for both a customer and all their orders are grouped in a single nested hierarchy named `Customers`. This differs from a one-to-many relationship where all customer information, as well as order information, would hierarchically exist at the same level and be related through the use of keys and keyrefs. For more information, see Tables, Columns, Keys, and Constraints in XML Schemas.

The follow example shows nested XML data:

```
<CustomerOrders>
  <Customers>
    <CustomerID>ALFKI</CustomerID>
    <Orders>
      <OrderID>10643</OrderID>
        <OrderDetails>
      <CustomerID>ALFKI</CustomerID>
      <OrderDate>1997-08-25</OrderDate>
    </Orders>
    <Orders>
      <OrderID>10692</OrderID>
      <CustomerID>ALFKI</CustomerID>
      <OrderDate>1997-10-03</OrderDate>
    </Orders>
    <CompanyName>Alfreds Futterkiste</CompanyName>
  </Customers>
  <Customers>
    <CustomerID>ANATR</CustomerID>
    <Orders>
      <OrderID>10308</OrderID>
      <CustomerID>ANATR</CustomerID>
      <OrderDate>1996-09-18</OrderDate>
    </Orders>
    <CompanyName>Ana Trujillo Emparedados y helados</CompanyName>
  </Customers>
</CustomerOrders>
```

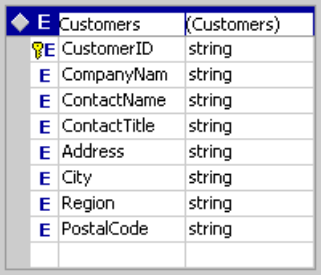
Creating Tables in XML Schemas

You can create tables and columns in XML Schemas in order to validate that table representations in XML data contain valid structure as well as valid data types. For more information about tables and columns, see Tables, Columns, Keys, and Constraints in XML Schemas.

Visual representation of a table in the XML Designer



E	Customers	(Customers)
E	CustomerID	string
E	CompanyNam	string
E	ContactName	string
E	ContactTitle	string
E	Address	string
E	City	string
E	Region	string
E	PostalCode	string

In XML Schemas, tables can be constructed manually or automatically with the XML Designer depending on the availability of a data source that represents the tables you need to validate within your application. You can also construct your schema both ways. For example: suppose you need to create a schema to validate XML data that includes a table with customer information and a table with customer feedback from your customer service department. Your organization already has the customer information table in an existing database; this can be created in your new schema automatically from your existing data source. The new table with customer feedback can be created manually and a relationship can be defined between the two tables.

Automatic Table Construction

You can use individual tables that are in existing data sources to easily construct schemas and datasets.

To automatically create table representations in XML Schemas using existing data sources.

1. In Solution Explorer, right click the project you want to add the dataset to, select **Add**, and then select **Add New Item**.
2. In the **Add New Item** dialog box, select **Dataset**, give the dataset a name, and then click **Open**.

   Visual Studio adds a new, blank schema file (.xsd) to the project as well as a corresponding **DataSet** class file.

   > **Note** The name you use will also be the name of the **DataSet** class file generated from the schema.

3. In Server Explorer, expand the **Data Connections** node and then expand the node for the connection to the data source you want to use.

   > **Note** If you don't already have a connection, create one. For more information, see Adding New Data Connections in Server Explorer.

4. In the **Connection** node, expand the node for the **Tables** you want to infer the schema structure from.
5. Drag the selected table onto the XML Designer.
6. Save the schema.

   Visual Studio creates the schema structure from the elements you specify and regenerates the corresponding class file for your typed dataset.

7. Repeat steps 4 and 5 to add more tables to your schema.

Manual Table Construction

If your schema requires table representations that have no available data sources to base them on, you can construct them manually with the XML Designer.

To manually create table representations in XML Schemas

1. In Solution Explorer, right-click the project you want to add the dataset to, select **Add**, and then select **Add New Item**.
2. In the **Add New Item** dialog box, select **Dataset**, give the dataset a name, and then click **Open**.

   Visual Studio adds a new, blank schema file (.xsd) to the project as well as a corresponding **DataSet** class file.

   > **Note** The name you use will also be the name of the **DataSet** class file generated from the schema.

3. Drag an **Element** from the **XML Schema** tab of the Toolbox onto the designer.

   A table definition is added to the schema,

4. Name the table by overwriting **Element1** in grid header of the element.
5. Move to a blank line in the table definition and select either **Element** or **Attribute** from the type drop-down. For more information, see Tables, Columns, Keys, and Constraints in XML Schemas.

   A column definition is added to the schema.

6. Assign a name and a data type to the new column definition.
7. Repeat Steps 3 through 5 for each table you want to add to the dataset.
8. Save the schema.

   The corresponding class file is regenerated to incorporate the changes you made.

Next Steps

- You can now define columns as primary and unique keys. For more information, see Creating Primary and Unique Keys in XML Schemas.
- You can also establish relationships between the tables in your schema. For more information, see Creating DataRelation Objects with the XML Designer.

If you need to make changes to the schema, you can use the XML Designer to add, edit, and remove elements.

See Also

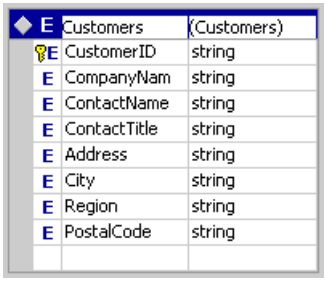
Relational Data in XML Schemas | Tables, Columns, Keys, and Constraints in XML Schemas | Nested Relationships in XML | Creating Primary and Unique Keys in XML Schemas | Creating One-to-Many Relationships in XML Schemas and Datasets | XML Schemas and Data | XML Schemas and the XML Designer | Creating XML Schemas and Datasets | XML Files | Introduction to Data Access with ADO.NET | Introduction to Datasets

Creating Primary and Unique Keys in XML Schemas

A primary key defines a column in a table as unique and required (null values are not allowed), whereas a unique key defines a column in a table as unique and optional (null values are allowed).

You designate columns in tables as keys, which allow you to create relationships and constraints. For more information about keys, see Tables, Columns, Keys, and Constraints in XML Schemas.

The following is a visual representation of a Key definition in the XML Designer



E	Customers	(Customers)
E	CustomerID	string
E	CompanyNam	string
E	ContactName	string
E	ContactTitle	string
E	Address	string
E	City	string
E	Region	string
E	PostalCode	string

To create a primary or unique key in an XML Schema or dataset

1. Right-click to the left of the row of the element you want to designate as a key. Approximately where the key glyph is in the picture above.
2. Click **Add** then click **New Key**.

   The **Edit Key** dialog box appears.

3. In the **Name** box, replace the default name with a name appropriate for this key.

   The **Selector** box and the **Field** area will default to the element you chose in Step 1.

4. If you need a key that is comprised of more than one column definition (a multipart key), select additional elements in the **Field** area.
5. If you need to allow the element to contain a null value, select **nullable**.
6. If you need a primary key, select **Primary Key**. Otherwise, a unique key will be created.

Next Steps

- Construct tables that will share this key data in order to define relationships. For more information, see Creating Tables in XML Schemas.
- You can now create a relationship with other tables that contain columns that are common to the key you just defined. For more information, see Creating DataRelation Objects with the XML Designer.

Deleting Primary Keys and Unique Keys

If your applications data requirements change, or if a key was inadvertently defined, you can delete primary and unique keys.

To delete an existing key

1. Select the row with the key definition you want to delete.
2. Right-click the row in the design grid with the key you want to delete.
3. Select **Delete Key** from the shortcut menu.

> **Note** If a row is part of multiple key definitions, the **Choose Key** dialog box will appear, allowing you to select and delete individual key definitions.

Relational Data in XML Schemas | Tables, Columns, Keys, and Constraints in XML Schemas | Creating Primary and Unique Keys in XML Schemas | Creating One-to-Many Relationships in XML Schemas and Datasets | XML Schemas and Data | XML Schemas and the XML Designer | Creating XML Schemas and Datasets | XML Files

Creating One-to-Many Relationships in XML Schemas and Datasets

You create a schema with one-to-many relationships when XML files contain related elements that are hierarchically at the same level. For more information, see Tables, Columns, Keys, and Constraints in XML Schemas.

> **Tip** If you have access to an XML file (.xml) that contains the structured data that your application needs to validate, see Creating XML Schemas from XML Files.

There are three main steps involved in creating an XML Schema that will be used to validate data that is structured in a one-to-many relationship.

To create a schema that represents a one-to-many relationship

1. Create the tables that will represent your applications data structure.
2. Create the primary keys, unique keys, and keyrefs.
3. Create the relationships between the tables.

For instructions on	See
Constructing Tables	Creating Tables in XML Schemas
Defining Keys	Creating Primary and Unique Keys in XML Schemas
Defining Relationships (keyrefs)	Creating DataRelation Objects with the XML Designer

See Also

Relational Data in XML Schemas | Tables, Columns, Keys, and Constraints in XML Schemas | Nested Relationships in XML | XML Schemas and Data | XML Schemas and the XML Designer | Creating XML Schemas and Datasets | XML Files | Introduction to Data Access with ADO.NET | Introduction to Datasets

Creating Nested Relationships in XML Schemas

You create a schema with nested relationships when XML data is represented by parent elements that contain nested child elements. For more information, see Nested Relationships in XML.

> **Tip** If you have access to an XML file (.xml) that contains the structured data that your application needs to validate then creating a schema can be accomplished by following the instructions for Creating XML Schemas from XML Files.

To construct a schema to validate nested data

1. Create the individual tables to represent the different hierarchies of data that your XML represents. For more information, see Creating Tables in XML Schemas.
2. Select the table that represents the nested child element and drag and drop it onto the table that represents the parent element.
3. If you have any tables that represent nested child elements, repeat Step 2.

The following example shows how to construct an XML Schema that validates nested data. In a nested relationship, the **OrderDetails** table is a nested child of the **Orders** table, which are both nested children of the **Customers** table.

```
<Customers>
   <CustomerID>ANATR</CustomerID>
   <CompanyName>Ana Trujillo Emparedados y helados</CompanyName>
   <Orders>
      <OrderID>10308</OrderID>
      <OrderDate>1996-09-18</OrderDate>
         <OrderDetails>
            <OrderWeight>20kg</OrderWeight>
            <ShipVia>International Air</ShipVia>
         </OrderDetails>
   </Orders>
</Customers>
```

To create a schema to illustrate a nested relationship

1. Following the instructions in the section Creating Tables in XML Schemas and create three tables. For this example there is no need to define columns, just create the tables and name them: **Customers**, **Orders**, and **OrderDetails**.
2. Click and drag the header of the **Orders** table and drop it onto the **Customers** table.

   An **Orders** column appears in the **Customers** table named **Orders**, and a line appears connecting the two tables.

3. Click and hold the header of the **OrderDetails** table and drop it onto the **Orders** table.

   An **OrderDetails** column appears in the **Orders** table named **OrderDetails**, and a line appears connecting the two tables.

   You can see the nested relationship illustrated on the designer by the lines that connect all three tables together, as well as the existence of the nested child tables as columns in each parent table throughout the hierarchy.

You have just created a schema that represents a nested relationship. More importantly switch to XML view (click the XML tab on the bottom of the design surface) and you can now see the apparent nested structure of the schema.

Relational Data in XML Schemas | Tables, Columns, Keys, and Constraints in XML Schemas | Nested Relationships in XML | Creating Tables in XML Schemas | Creating Primary and Unique Keys in XML Schemas | XML Schemas and Data | XML Schemas and the XML Designer | Creating XML Schemas and Datasets | XML Files

Walkthrough: Creating a Dataset with Tables, Keys, and One-to-Many Relationships

In this walkthrough you will create a dataset to validate data in a one-to-many relationship (a one-to-many relationship can also be called a *keyed relationship*). It will take you through the process of creating a new Visual Basic or Visual C# project and adding a new Dataset item to it. Then you will create complex type elements that represent data tables with columns. You will learn how to define primary keys in tables. Finally, you will learn how to create relationships between tables based on the defined keys. When complete you will be able to examine the underlying XML code that was created by the XML Designer, in order to understand how datasets express keyed relationships in native XML.

This walkthrough will include creating tables, primary keys, and relationships and will consist of the three major sections outlined below:

1. **Add a Dataset to a project and create three tables.**
   a. Create a Customers table.
   b. Create an Orders table.
   c. Create an OrderDetails table.
2. **Create two primary keys.**
   a. Create a primary key in the Customers table.
   b. Create a primary key in the Orders table.
3. **Create two relationships (DataRelation objects).**
   a. Create a relationship between the Customers table (one) and the Orders table (many).
   b. Create a relationship between the Orders table (one) and the OrderDetails table (many).

Create a New Windows Application Project and Add a New Dataset to it

To create and name a new project

1. From the **File** menu, point to **New**, and then click **Project** to display the **New Project** dialog box.
2. Depending on what language you want to use, select **Visual Basic Projects** or **Visual C# Projects** in the **Project Types** pane, and then select **Windows Application**.
3. Name the project **KeyedRelationshipWalkthrough** and then click **OK** to create the project.

Because this walkthrough requires a dataset, you need to add one to your project.

To add a new Dataset item to the project

1. From the **Project** menu, select **Add New Item**.

   The **Add New Item** dialog appears.

2. From the Templates area of the **Add New Item** dialog box select **Dataset**.
3. Name the Dataset **CustomerOrders** and click **Open**.

   Visual Studio will add a file called **CustomerOrders.xsd** (Visual Basic) and **CustomerOrders.vb** (Visual Basic) or **CustomerOrders.cs** (Visual C#) to the project and automatically load it into the designer.

4. From the **Project** menu, if it is not already, select **Show All Files**. (There will be a visible border around the icon when selected)
5. In Solution Explorer expand the **CustomerOrders.xsd** node.

   You can now see the **CustomerOrders.vb** (Visual Basic) or **CustomerOrders.cs** (Visual C#) file that was created in step 3 above. This is the actual dataset, or more accurately a dataset class. The **CustomerOrders.xsd** file is an XML Schema that will define the structure of the dataset.

Create Three Tables in the Dataset

This section will explain how to add elements to your dataset that will represent data tables.

To create the Customers table

1. From the **XML Schema** tab of the Toolbox, select an **element** and drop it onto the designer.

2. In the top cell to the right of the '**E**' highlight the default name of **element1** and type **Customers**.
3. Using the TAB key, navigate to the center cell of the next row and type **CustomerID**. The data type is string for this element, which is the default so you can just leave it. However, if you needed to assign a data type that was not a string, you would use TAB to navigate to the drop-down list to the right of the desired element and select the appropriate data type.

   Note Also notice how you navigated past the small cell to the left of the cell that said **element1**. That is the cell where you choose other types of elements, such as attributes, and so on. Because the default value is **E** for element we can leave that set as well.

4. Repeat Step 3 to create new rows in the Customers element for the following:

Element name	Data type
CompanyName	**string**
ContactName	**string**
ContactTitle	**string**
Address	**string**
City	**string**
Region	**string**
PostalCode	**string**

To create the Orders table

1. From the **XML Schema** tab of the Toolbox select an element and drop it onto the designer.
2. In the top cell to the right of the '**E**' highlight the default name of **element1** and type **Orders**.
3. Using the TAB key navigate to the center cell of the next row and type **OrderID** and set the data type to string.
4. Repeat Step 3 and create new rows in the Orders element for the following:

Element name	Data type
CustomerID	**string**
OrderDate	**date**
ShippedDate	**date**
ShipVia	**string**

To create the OrderDetails table

1. From the **XML Schema** tab of the Toolbox select an element and drop it onto the designer.
2. In the top cell to the right of the '**E**' highlight the default name of **element1** and type **OrderDetails**.
3. Using the TAB key, navigate to the center cell of the next row and type **OrderID** and set the data type to string.
4. Repeat Step 3 and create new rows in the OrderDetails element for the following:

Element name	Data type
ProductID	integer
UnitPrice	decimal
Quantity	short

Create the Two Primary Keys in the Tables

This section will explain how to designate columns in the tables you created in the previous section as primary keys. In order to create relationships you must have at least one key defined in the parent table (the parent table is the table that represents the one side of a one-to-many relationship).

To create the primary key in the Customers table

1. In the **Customers** table, select the **CustomerID** row by clicking to the left of the **E**.
2. Right-click, point to **Add**, select **New key** from the shortcut menu.
3. The **Edit Key** dialog box appears.
4. Change the name of the key to **CustomersIDKey**.
5. The Element drop-down list box should be set to **Customers**, which indicates that you are in the Customers table.

   Note The **Customers** table is really the
   Customers
   element that is defined as a complex type; it is complex type elements that represent tables in XML Schemas and

Datasets. For more information see Creating One-to-Many Relationships in XML Schemas and Datasets.

6. In the Fields area, select **CustomerID** from the drop-down list. If you right-clicked on the **CustomerID** row to add the key this should be the default value, if you clicked on a different row you will need to select the **CustomerID** element.

   Note The **Fields** area is where you select which element (within the complex type definition of your table element) you want to define as the Key.

7. Select the **Dataset primary key** check box, to define this key as a primary key.

   Note If you did not select the **Dataset primary key** checkbox then the key would be defined as a unique key, instead of a primary key.

8. Click **OK** to close the Edit Key dialog box.

   A key icon is placed on the **CustomerID** row to identify it as a key.

To create the primary key in the Orders table

1. In the **Orders** table select the **OrderID** row by clicking to the left of the **E**.
2. Right-click the selected row, point to **Add**, and select **New key** from the shortcut menu.

   The **Edit Key** dialog box appears.

3. Change the name of the key to **OrdersIDKey**.
4. The Element drop-down should be set to **Orders**, which indicates that you are in the Orders table.
5. In the Fields area, select **OrderID** from the drop down list. If you right-clicked on the **OrderID** row to add the key, this should be the default value. If you clicked on a different row, you will need to select the correct element.
6. Select the **Dataset primary key** checkbox to define this key as a primary key.
7. Click **OK** to close the Edit Key dialog box.

   A key icon is placed on the **OrderID** row to identify it as a key.

You now have the keys defined that will be used to define the relationships between the tables. You might be wondering why we did not define a key in the **OrderDetails** table. At the beginning of this section it said, "In order to create relationships you must have at least one key defined in the parent table (the parent table is the table that represents the one side of a one-to-many relationship)." The **OrderDetails** table does not represent the one side in any relationships in this dataset, therefore no key definition is required.

Create the Two Relationships Between the Tables

A relationship is the association between a keyed column in one table and the many records that have an associated column in another table. In XML Schemas relationships are defined with the `keyref` element. This section will explain how to define these relationships.

To create a relationship (DataRelation object) between the Customers and Orders table

1. Right-click anywhere on the **Orders** table, point to **Add**, and select **New Relation** from the shortcut menu.

   The **Edit Relation** dialog box appears.

   Note Be sure to add the New Relation to the table representing the many side of a one-to-many relationship (in this case add the **Relation** to the **Orders** table).

2. The **Edit Relation** dialog box assigns a default name of **CustomersOrders**. You can leave this as is.
3. The **Parent Element** should be set to **Customers**. The parent is the element (or table) that represents the one side in a one-to-many relationship. In this case the **Customers** table represents the one side.
4. The **Child Element** should be set to **Orders**. The child is the element (or table) that represents the many side in a one-to-many relationship. In this case, the **Orders** table represents the many side.
5. The Key should be set to **CustomersIDKey** that we defined earlier.

   Note When creating a one-to-many relationship the key definition needs to be in the Parent table, because that is the table that contains the unique value.

6. The key fields are read only and contain the key column or columns defined in the key definition.

Note Multipart keys are key definitions that have multiple columns in a table that are part of the key definition. If a multipart key were defined in **CustomersIDKey** then all the columns (or fields) would be listed in the key fields area. This walkthrough does not include any multipart keys.

7. The Foreign Key Fields area is where you select the field in the child table that is equivalent to the key in the Parent table. This field should be set to **CustomerID** to match the key field in the parent table.
8. Click **OK** to accept the remaining default settings.

   A **DataRelation** object is created and a visual representation appears on the design surface.

To create a relationship (DataRelation object) between the Orders and OrderDetails table

1. Right-click anywhere on the **OrderDetails** table, point to **Add**, and select **New Relation** from the shortcut menu.

   The **Edit Relation** dialog box appears.

   Note Be sure to add the New Relation to the table representing the many side of a one-to-many relationship (in this case add the Relation to the **OrderDetails** table).

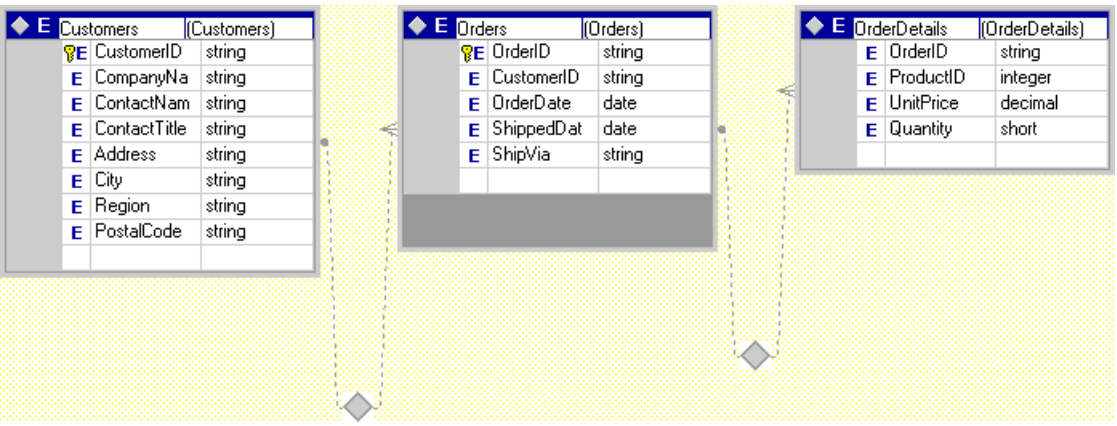
2. Change the default name of **CustomersOrderDetails** to **OrdersOrderDetails** to reflect the proper tables in the relationship.
3. The **Parent Element** should be set to **Orders**.
4. The **Child Element** should be set to **OrderDetails**.
5. The **Key** should be set to **OrdersIDKey**, which was defined earlier.

   The key fields are read only and contain the key column or columns defined in the key definition selected in step 5.

6. The **Foreign Key Fields** area is were you select the field in the child table that is equivalent to the key in the Parent table. Verify that this field is set to **OrderID** to match the key field in the parent table.
7. Click **OK** to accept the remaining default settings.

   A **DataRelation** object is created and a visual representation appears on the design surface.

This is how your dataset should look in the XML Designer:



You have just created three related tables in a Dataset. If you swtich to XML view, your code should be equivalent to the following. What is important to note is how native XML is structured in a one-to-many (or keyed) relational model. As you can see the `Customers`, `Orders`, and `OrderDetails` all exist hierarchically at the same level, as direct children of the `CustomerOrders` element. It is this `CustomerOrders` element that represents the dataset.

Note Notice how the keys are defined hierarchically as children of the CustomerOrders element. It is very important to understand why the key definitions are not located as nested children within the element that represents the table the key is defined in. If that were the case, the key would only be unique for each record, not for all records in the table. By having the key defined within the dataset itself (the CustomerOrders element) the key controls uniqueness throughout the entire dataset.

```
<xs:schema id="CustomerOrders" targetNamespace="http://tempuri.org/CustomerOrders.xsd" elemen
tFormDefault="qualified" xmlns="http://tempuri.org/CustomerOrders.xsd" xmlns:mstns="http://te

XML Files

XML files contain both the actual data (or content) and the elements that identify the data. The XML Designer provides two ways to view and work with XML documents, XML view and Data view. XML view, as its name implies, is actual XML code (or XML markup). Data view interprets the XML source and displays the contents in a data grid. Using the XML designer in XML view provides both color-coding, which makes the code easy to read, and IntelliSense, for helping to locate syntax errors. Additionally, if a schema is associated with the XML file the statement completion feature is enabled, as well as an option to validate the XML data against the schema.

> **Note** There are some instances of XML documents where Data view is disabled. This occurs when the XML data cannot be mapped into the dataset. If your XML document is structured in this way, changing to Data view will present a message stating; "Although this XML document is well formed, it contains structure that Data View cannot display."

Creating New XML Files

Because XML is an applicable format for so many different applications, there is no one specific reason why someone would create a new XML document. If you need to create an XML file from scratch, there are a couple of XML Designer specifics to take into account.

- There are some instances of XML documents where Data view is disabled. This occurs when the XML source cannot be logically interpreted into structured data. If your XML document is structured in this way, changing to Data view will present a message stating, "Although this XML document is well formed, it contains structure that Data view cannot display."
- When creating new XML documents, you always begin in XML view, working with XML source code. After you have added the initial tags and content, if your XML document can be interpreted into structured data, you can then change to Data view and use the data grid to add data to your XML file.

To create an XML file in Visual Studio

1. From the **Project** menu, select **Add New Item.**
2. In the **Add New Item** dialog box, select **XML File**.
3. Type a name for your XML file.

   Visual Studio adds a new, blank XML file (.xml) to the project, automatically loads it into the XML Designer, and presents it in XML view.

4. Add XML content to your file.

Next Steps

After you have created your XML file, you may want to:

- Create a schema and dataset based on the structure of your XML. For more information, see Creating XML Schemas from XML Files.
- Associate a schema with it. For more information, see Assigning Schemas to XML Files.
- Verify that it is valid against a schema. For more information, see Checking for Well-Formed and Valid XML.

Assigning Schemas to XML Files

You assign a schema to an XML file when you want to verify that the content of an XML file is made of the proper data types and is presented in the proper structure. In order to validate an XML file with a schema, you must create a link between the schema file and the XML file. This link is defined in the **targetSchema** property of the .xml file and when set is added as a namespace reference within the contents of the XML document.

To create the association between schemas and XML documents

1. Load an XML file into the XML Designer.
2. Change to XML view by clicking the **XML** tab on the bottom of the designer.
3. In the Properties window select **DOCUMENT** from the drop-down list.
4. Set the **targetSchema** property to the schema to be associated with the XML document.

> **Note** If the XML Schema is a file in your project it will be available in the **targetSchema** property drop-down list. If it is not in your project, type the Uniform Resource Identifier (URI) of the schema that will be used to validate your XML document.

To remove the association between an XML Schema and an XML document

1. Load the XML file into the XML Designer.
2. Change to XML view by clicking the **XML** tab at the bottom of the designer.
3. In the Properties window, select **DOCUMENT** from the drop-down list.
4. Clear the contents of the **targetSchema** property.

Next Steps

Now that you have associated a schema to an XML file, you may want to:

- Validate your XML file. For more information, see Checking for Well-Formed and Valid XML.
- Create a dataset from the schema that is associated with the XML file. For more information, see Creating ADO.NET Typed DataSets from Schemas.

Checking for Well-Formed and Valid XML

There are two inherently different ways to verify whether XML files are coded correctly. All XML files must be well formed, and if an XML file has an associated schema, then the structure and content must also be deemed valid.

- **Well-formed** – The XML code must be syntactically correct or the XML parser will raise an error.
- **Valid** – If the XML file has an associated XML Schema, the elements must appear in the defined structure and the content of the individual elements must conform to the declared data types specified in the schema.

The XML Designer can be used to verify that XML files are both well formed and valid.

To check for well-formed or valid XML

> **Note** In order to check that XML files are valid, they must have an associated XML Schema. For more information on associating a schema with your XML file, see Assigning Schemas to XML Files.

1. Load the XML file you want to check into the XML Designer.
2. From the **XML** menu select **Validate XML Data**.
3. The status bar will indicate if errors were found in your XML file.
4. If errors were found, view the Task List For more information.

Creating XML Schemas from XML Files

You create schemas based on existing XML files when you want to validate that other XML files conform to the same data structure and data type restrictions as the original XML file.

> **Tip** To create an ADO.NET dataset from an XML file, you must first create a schema and then generate a dataset from that schema. For more information, see Creating ADO.NET Typed Datasets from Schemas.

> **Note** There are some instances of XML documents that schemas and datasets cannot be created from. Although the XML would be considered well formed, trying to create a schema will generate a **Failed to Create Schema** error if the contents cannot be logically interpreted into structured data.

To create a new XML Schema based on an existing XML Document

1. Load an XML document (.xml file) into the XML Designer.
2. From the **XML** menu click **Create Schema**.

   An XML Schema (.xsd file) is added to the current project with the same name as the original XML file.

3. Load the newly created XML Schema (.xsd file) into the XML Designer.
4. Verify and edit the data types that were assigned when creating the schema.

   > **Note** When a schema is inferred from an existing XML document, all the data types are initially set to **string**, so you must edit the data types according to the content requirements of your XML data.

5. If you need to make changes to the schema, you can use the XML Designer to add, edit, and remove elements.

Next Steps

- If the schema you just created requires primary or unique keys defined then you should create those now. For more information, see Creating Primary and Unique Keys in XML Schemas.
- If the schema you just created requires relationships defined between tables then you should create those now. For more information, see Creating DataRelation Objects with the XML Designer.
- Since the XML Designer can create datasets based on the structure of existing XML Schemas, you can now generate a new dataset based on the schema you created in the previous steps. For more information, see Creating ADO.NET Typed Datasets from Schemas.

Walkthrough: Creating an XML File with an Associated XML Schema

This walkthrough will illustrate the capabilities of working with XML files that have associated schemas. It will take you through the process of creating an XML file and an XML Schema based on the XML Schema definition language (XSD). Then you will create an association between the XML Schema and the XML file. After this association is established, you will work on the XML file in XML view in order to see the advanced capabilities of the XML editor. For this walkthrough the XML file will represent a list of companies. You will see how the XML file contains the data whereas the XML Schema only defines that data.

> **Note** By associating an XML Schema with your XML file, statement completion is enabled in the XML editor.

Creating a New Windows Application Project

To begin this walkthrough you will first need to create a new Windows Application in Visual Basic or Visual C#.

To create a new project and name it "XMLCustomerList"

1. From the **File** menu, point to **New**, and then click **Project** to display the **New Project** dialog box.
2. Depending on what language you want to use, select **Visual Basic Projects** or **Visual C# Projects** in the **Project Types** pane, and then select **Windows Application**.
3. Name the project **XMLCustomerList**, then click **OK** to create the project.

   Visual Studio will add the XMLCustomerList project to Solution Explorer.

Add a New XML File item to your Project

Because this walkthrough requires an XML file, you need to add one to your project.

To add a new XML file item to the project

1. From the **Project** menu, select **Add New Item**.

   The **Add New Item** dialog box appears.
2. In the Templates area of the **Add New Item** dialog box, select **XML File**.
3. Name the XML file **CustomerList**, and then click **Open**.

   Visual Studio will add a file called **CustomerList.xml** to the project and automatically load it into the designer.

Add a New XML Schema item to your Project

Because this walkthrough requires an XML Schema, you need to add one to your project.

To add a new XML Schema item to the project

1. From the **Project** menu, select **Add New Item**.

   The **Add New Item** dialog appears.
2. In the Templates area of the **Add New Item** dialog box select **XML Schema**.
3. Name the schema **CustomerListSchema** and then click **Open**.

   Visual Studio will add a file called **CustomerListSchema.xsd** to the project and automatically load it into the designer.

Add a Simple Type Definition to your Schema

Now you need to define the elements that will contain the data in your XML file. Because an XML Schema defines the data in an associated XML file, you create the element definitions in the schema.

The first definition will be a simple type element that will be used to define a standard US postal code (ZIP code). For this walkthrough we will use 5-digit codes only.

To create a simple type element that represents a 5 digit postal code

1. From the **XML Schema** tab of the Toolbox, drag a **simpleType** onto the design surface.
2. Select the default name **simpleType1** and rename this type to **postalCode**.

3. Use the TAB key to navigate one cell to the right and select **positiveInteger** from the drop-down list.
4. Use the TAB key to navigate to the next row.
5. Click the drop-down box.

   The only choice is facet. This is because simple types cannot include elements or attributes as part of their content models. Only facets can be used to build simple types.

6. Use the TAB key to navigate one cell to the right and select **pattern** from the drop-down list.
7. TAB over one cell to the right again and type **\d{5}**.

   The pattern facet allows you to enter regular expressions. The regular expression \d{5} says that the contents of the postalCode type is restricted to 5 digits. Regular expressions are beyond the scope of this walkthrough, but you can see how you can use the pattern facet in conjunction with the chosen data type to only allow specific data in a simple type.

   If you switch your schema to XML view you should see the following code within the root level schema tags (that means the code sample does not include the actual declaration part of the schema, nor does it include the actual schema tags which are called the root or document level tags):

```
<xs:simpleType name="postalCode">
   <xs:restriction base="xs:positiveInteger">
      <xs:pattern value="\d{5}" />
   </xs:restriction>
</xs:simpleType>
```

8. From the **File** menu, select **Save All**.

Add a Complex Type Definition to your Schema

The next definition will be a complex type element that will be used to define an address. As part of this complex type definition, we will use the simple type created in the previous steps.

To create a complex type element that represents a standard US address

1. Switch back to **Schema** view.
2. From the **XML Schema** tab of the Toolbox, drag a **complexType** onto the design surface.
3. Select the default name **complexType1** and rename this type to **usAddress**. Do not select a data type for this element.
4. Using the TAB key, navigate to the next row.
5. Click the drop-down list box to see the many choices of elements you can add to a complex type. You can select element, but for the rest of the walkthrough you will just TAB over this cell because element is the default.
6. Using the TAB key, navigate one cell to the right and type **Name**.
7. TAB one cell to the right and set the data type to **string**.
8. Repeat Steps 4 – 7 and create new rows in the `usAddress` element for the following:

Element name	Data type
Street	string
City	string
State	string
Zip	postalCode

   Notice the data type that is assigned to the Zip element. It is the `postalCode` simple type you created previously.

   If you switch to XML view, you should see the following code within the root level schema tags (that means the code sample does not include the actual declaration part of the schema, nor does it include the actual schema tags which are called the root or document level tags):

```
<xs:simpleType name="postalCode">
   <xs:restriction base="xs:positiveInteger">
      <xs:pattern value="\d{5}" />
   </xs:restriction>
</xs:simpleType>
<xs:complexType name="usAddress">
```

```
      <xs:sequence>
         <xs:element name="Name" type="xs:string" />
         <xs:element name="Street" type="xs:string" />
         <xs:element name="City" type="xs:string" />
         <xs:element name="State" type="xs:string" />
         <xs:element name="Zip" type="postalCode" />
      </xs:sequence>
   </xs:complexType>
```

You have now defined two separate types that can be used in element definitions as well as types.

9. From the **File** menu, select **Save All**.

Add the Main Elements to your Schema

Now that you have defined some data types lets construct the actual data definition for the XML file you will be creating. The XML file will contain the data for the customer list, so lets create the actual element that will define the data that will be valid in the XML file.

To create the Customer element

1. Switch to **Schema** view.
2. From the **XML Schema** tab of the Toolbox, drag an **element** onto the design surface.
3. Select the default name **element1** and rename this to **customer**. Do not select a data type for this element.
4. Using the TAB key navigate to the center cell of the next row, and type **CompanyName**.
5. TAB one cell to the right and set the data type to **string**.
6. Repeat Steps 4 – 5 and create new rows in the `Customer` element for the following:

Element name	Data type
ContactName	string
Email	string
Phone	string
BillToAddress	usAddress
ShipToAddress	usAddress

Notice the data type that is assigned to the BillToAddress as well as the ShipToAddress elements. It is the `usAddress` complex type created previously. We could have defined simple types for the Email, Phone elements and so on.

If you switch your schema to XML view, you should see the following code within the root-level schema tags (that means the code sample does not include the actual declaration part of the schema, nor does it include the actual schema tags which are called the root or document level tags):

```
   <xs:simpleType name="postalCode">
      <xs:restriction base="xs:positiveInteger">
         <xs:pattern value="\d{5}" />
      </xs:restriction>
   </xs:simpleType>
   <xs:complexType name="usAddress">
      <xs:sequence>
         <xs:element name="Name" type="xs:string" />
         <xs:element name="Street" type="xs:string" />
         <xs:element name="City" type="xs:string" />
         <xs:element name="State" type="xs:string" />
         <xs:element name="Zip" type="postalCode" />
      </xs:sequence>
   </xs:complexType>
   <xs:element name="Customer">
      <xs:complexType>
         <xs:sequence>
            <xs:element name="CompanyName" type="xs:string" />
            <xs:element name="ContactName" type="xs:string" />
```

```
            <xs:element name="Email" type="xs:string" />
            <xs:element name="Phone" type="xs:string" />
            <xs:element name="ShipToAddress" type="usAddress" />
            <xs:element name="BillToAddress" type="usAddress" />
         </xs:sequence>
      </xs:complexType>
   </xs:element>
```

7. From the **File** menu, select **Save All**.

In order to allow multiple instances of customer data within the XML document, we will create an element named `customerList` that will contain all the individual `customer` elements.

To create the customerList element

1. From the **XML Schema** tab of the Toolbox, drag an **element** onto the design surface.
2. Select the default name **element1** and rename this to **customerList**. Do not select a data type for this element.
3. Select the **customer** element (created previously) and drag it onto the **customerList** element.

   The individual design grids bind to represent the hierarchical structure of the data.

4. From the **File** menu, select **Save All**.

Associating the Schema and the XML file

In this part of the walkthrough, you will start working with the XML file. Within the XML file you will add a reference to the schema you just created.

To create an association between the XML file and the XML Schema

1. In Solution Explorer double-click the CustomerList.xml file.
2. The XML file opens in the designer in XML view.
3. In the Properties window, click the cell to the right of the **targetSchema** property and select **http://tempuri.org/CustomerListSchema.xsd**.

   Visual Studio adds a reference to the schema in the CustomerList.xml file and adds the `<customerList>` tags.

Adding Data to your XML file

The XML file is now ready for data. By associating a schema with your XML file, the XML editor now is aware of the valid elements that can be included in your XML file, as well as providing a fromatted grid in data view.

To add data to the customerList.xml file

1. In **XML** view of the **customerList.xml** file, position the cursor between the opening and closing `<customerList>` tags (Opening tag = `<customerList>` Closing tag = `</customerList>`).
2. Type **<**. Select the `Customer` element.
3. Type **>** to close the tag.
4. Type **<**, and select **CompanyName** from the list of valid elements.
5. Type **>** to close the tag.
6. Type **Blue Yonder Airlines** as the company name.
7. Switch to **Data** view.
8. Type **Nate Sun** in the **ContactName** field in the grid.
9. Complete the record by adding data into the other fields in the grid.
10. Switch back to **XML** view.

    The data from the grid is now properly formatted as XML.

Next Steps

Some common next steps include:

- Add some data in XML view and then switch to Data view. Explore the different ways to add data to your XML files using the

XML Designer.

- After adding some data, validate your document.
- Generate a dataset from your schema.

Programming with Components

Components shorten programming time and produce more robust applications, by allowing you to assemble applications from tested, standardized components. The designer architecture in Visual Studio .NET lets you assemble nonvisual component classes as easily as you assemble Visual Basic forms. The following sections explain how to create your own components, and how to assemble them from the sophisticated components in the .NET Framework classes.

In This Section

Component Programming Walkthroughs
Provides a list of the walkthroughs available for component creation and implementation.
Code for Component Programming
Provides a list of code examples for common tasks.
Troubleshooting Control and Component Authoring
Explains how to fix common problems.
Component Authoring
Describes component architecture, terminology, design, and implementation.
COM Interoperability in Visual Basic and Visual C#
Provides links to information about the concepts and implementation details for interoperating between COM and .NET objects.
Creating Messaging Components
Introduces components that interact with Microsoft Message Queuing system resources.
Creating File System and Timer Components
Introduces components that respond to changes to files and directories, raise events on a schedule, or monitor and interact with Windows processes.
Creating System Monitoring Components
Introduces components that interact with Windows performance counters and event logs.
Creating Active Directory Components
Introduces components that interact with the Active Directory, allowing you to perform administrative directory tasks within your application.
Creating Installation Components
Introduces installation components, which allow you to execute custom actions when your application is deployed.
Programming with Office
Provides information on using Microsoft Office and Visual Studio .NET as part of your business application.

Component Programming Walkthroughs

Walkthroughs give step-by-step instructions for common scenarios, which makes them a good place to start learning about the product or a particular feature area.

The following walkthroughs will help orient you to the use of components, user controls, and threading in your Visual Basic and Visual C# applications:

Authoring a Component with Visual Basic .NET
: Shows the development of a simple component in Visual Basic, illustrating the interaction between client and component, object lifetime and circular references, debugging clients and components, and the use of shared methods and instance methods.

Authoring a Component with Visual C#
: Shows the development of a simple component in Visual C#, illustrating the interaction between client and component, object lifetime and circular references, debugging clients and components, and the use of shared methods and instance methods.

Creating Your Own Collection Class
: Shows how you can create your own collection classes by inheriting from one of the many .NET Framework collection classes and adding code to implement your own custom functionality.

Authoring a User Control with Visual Basic .NET
: Shows the development of a simple control in Visual Basic that inherits from the **UserControl** class, and how to inherit from an established user control.

Authoring a User Control with Visual C#
: Shows the development of a simple control in Visual C# that inherits from the **UserControl** class, and how to inherit from an established user control.

Inheriting from a Windows Forms Control with Visual Basic .NET
: Shows the development of a simple control in Visual Basic that inherits from a pre-existing Windows Forms control.

Inheriting from a Windows Forms Control with Visual C#
: Shows the development of a simple control in Visual C# that inherits from a pre-existing Windows Forms control.

Authoring a Simple Multithreaded Component with Visual Basic
: Demonstrates the development of a simple multithreaded component in Visual Basic, explaining how threads work and how to coordinate multiple threads in your component.

Authoring a Simple Multithreaded Component with Visual C#
: Demonstrates the development of a simple multithreaded component in Visual, explaining how threads work and how to coordinate multiple threads in your component.

Creating a Queue and Working with Messages
: Describes how to use a **MessageQueue** component instance to interact with Windows message queues.

Creating a Message Queue Transaction with COM+ Services
: Shows how you can use COM+ services to wrap your message in a transaction.

Exploring Event Logs, Event Sources, and Entries
: Describes how to use an **EventLog** component instance to interact with existing logs, create custom logs, and read and write values to logs.

Retrieving Categories and Counters
: Describes how to use a **PerformanceCounter** component instance to retrieve lists of Windows performance counter categories on a server.

Changing and Retrieving Performance Counter Values
: Describes how to use a **PerformanceCounter** component instance to retrieve and set raw and calculated values from a Windows performance counter.

Managing a Windows Process
: Describes how to use the **Process** component to monitor and interact with Windows processes on a server.

Reacting to File System Events
: Describes how to use a **FileSystemWatcher** component instance to monitor files and directories and react when changes occur.

Adding ActiveDirectory Objects
: Describes how to use the **DirectorySearcher** component to interact with Active Directory file system structures.

Installing an Event Log Component
: Describes how to use an installation component to configure server resources needed for your **EventLog** component instance.

Visual Basic Code Example Topics

Code for Component Programming

This topic is designed to help you find code that demonstrates how to perform common component programming tasks in Visual Basic .NET. The following categories are represented in the list below:

• Component Authoring • Multithreading • Containers and Sites • Exception Handling • Component Security • User Assistance • User and Custom Controls	• Messaging Components • File System and Timer Components • Performance Counter Components • Event Log Components • Services and Processes • Active Directory Components • Related Code Examples

You can also find sample code for component programming in the following locations:

- General Programming Example Topics
- General .NET Framework Example Topics
- Visual Basic Sample Applications
- Visual Basic QuickStarts and Other Samples
- .NET Framework Reference Information

Component Authoring

Example of...

Creating a simple component

Declaring a method in a component

Declaring an overloaded method in a component

Declaring and raising events in components

Creating named constants for components

Implementing properties in components

Implementing default properties in components

Exposing properties of contained objects

Saving and retrieving the state of a component

Creating abstract classes

Creating interfaces

Implementing existing interfaces

Displaying forms from components

Allowing for communication between components in an assembly

Containers and Sites

Example of...

Creating component containers

Extending component containers

Implementing nested classes

Linking dependent objects

Implementing collection properties

Multithreading

Example of...

Creating a simple multithreaded component

Creating a new thread of execution

Creating a lock on a thread

Writing to event logs from multithreaded components

Manipulating controls from threads

Exception Handling

Example of...

Throwing exceptions from components

Handling exceptions in components

Component Security

Example of...

Adding security attributes to your components

Adding imperative security checks to your components

User Assistance

Example of...

Displaying a help file for your component

Providing descriptive metadata for your component

Providing descriptive metadata for component properties, methods, and events

User and Custom Controls

Example of...

Creating a user control for Windows Forms applications

Inheriting from a Windows Forms control

Exposing Properties of Constituent Controls

Implementing Methods in Custom Controls

Painting and Rendering Custom Controls

Painting and Rendering Constituent Controls

Making Controls Invisible at Run Time

Docking and aligning controls

Adding your controls to the toolbox

Adding tooltips to your controls

Giving your control a transparent background

Messaging Components

Example of...

Creating a simple message queuing application

Creating public and private queues

Purging a queue's contents

Instantiating components to interact with a message queue

Sending simple messages

Sending complex messages

Sending messages to a journal queue

Specifying the format for received messages

Taking messages out of a queue

Peeking at queue contents

Receiving messages asynchronously

Sending transactional messages

Retrieving lists of available messages

Retrieving lists of available queues

File System and Timer Components

Example of...

Creating a simple application that monitors the file system

Instantiating components to monitor files or directories

Specifying what to monitor for

Handling file system events

Pausing a thread for continuation when a file system event occurs

Creating and configuring server-based timers

Monitoring server-based timers

Performance Counter Components

Example of...

Creating a simple application that retrieves existing categories and counters

Creating a simple application that writes to a counter

Instantiating components to interact with performance counters

Specifying the counter to monitor

Creating custom counters

Creating counter categories

Determining if a counter or category already exists

Adding and removing counter instances

Writing values to performance counters

Retrieving raw values from a performance counter

Retrieving calculated values from a performance counter

Sampling performance counter values

Retrieving lists of categories and counters

Event Log Components

Example of...

Determining if an event log exists

Creating custom event logs

Deleting event logs

Clearing event log entries

Instantiating a component to interact with an event log

Adding your application as a source of events

Writing entries to event logs

Reading entries from event logs

Handling event log events

Services and Processes

Example of...

Instantiating components to interact with services

Stopping, starting, and pausing services

Retrieving lists of services

Connecting to processes on another computer

Binding to existing processes

Starting processes

Stopping processes

Determining if a process is responding

Determining if a process has exited

Viewing running processes

Waiting for a process to complete an action

Investigating memory usage for a process

Investigating thread usage for a process

Creating a simple application that monitors a process

Active Directory Components

Example of...

Instantiating a component to interact with an Active Directory heirarchy

Creating nodes in a heirarchy

Removing heirarchy nodes

Searching a heirarchy

Creating a simple application that creates Active Directory objects

Troubleshooting Control and Component Authoring

This topic lists common problems that arise when developing components and controls. For more information, see Authoring Components.

Cannot Add Control to Toolbox

If you want to add a custom control that you created in another project or a third-party control to the Toolbox, you must do so manually.

To add a control to the Toolbox

1. Right-click the **Toolbox** and choose **Add/Remove Items** from the shortcut menu.

   The **Customize Toolbox** dialog box opens.

2. Add the component:

   - If you want to add a .NET component or control, click the **.NET Framework Components** tab.

     – or –

   - If you want to add a COM component or ActiveX control, click the **COM Components** tab.

3. If your control is listed in the dialog box, make sure it is selected, then click OK.

   The control is added to the Toolbox.

4. If your control is not listed in the dialog box, do the following:
   a. Click the **Browse** button.
   b. Browse to the folder that contains the .dll file that contains your control.
   c. Select the control and click **Open**.

      Your control appears in the dialog box.

   d. Make sure your control is selected, then click OK.

      Your control is added to the Toolbox.

Cannot Debug My Windows Forms User Control or Component

Windows Forms user controls, custom controls, and components are not stand-alone projects. They must be hosted by an application such as a Windows Forms project. To debug a control or component, you must add it to a Windows Forms project.

To debug a control or component

1. From the **Build** menu, click **Build Solution** to build your solution.
2. From the **File** menu, choose **Add Project** then **New Project** to add a test project to your application.
3. In the **Add New Project** dialog box choose **Windows Application** for the type of project.
4. Right-click the References node and click **Add Reference** on the shortcut menu to add a reference to the project containing the control or component.
5. Create an instance of your control or component in the test project. If your component is in the toolbox, you can drag it to your designer surface, or you can create the instance programmatically as shown in the following example:

   ```
   ' Visual Basic
   Dim Component1 As New MyNeatComponent()

   // C#
   MyNeatComponent Component1 = new MyNeatComponent();
   ```

   You can now debug your control or component as normal.

For more information on debugging, see Debugging.

Event Fires Twice in Inherited Control or Component

This is likely due to a duplicated **Handles** clause. For more information, see Troubleshooting Inherited Event Handlers in Visual Basic .NET.

Component Authoring

The designers in Visual Studio .NET make it easy to author components and you can extend their functionality to provide a better programming experience for users of your components.

> **Visual Basic Note** Visual Basic programmers should be familiar with object-based programming concepts. It is not necessary to have a thorough understanding of inheritance, but you may find it useful to refer to Inheritance.

Walkthroughs in Visual Basic and Visual C#
Lists all the step-by-step topics that use Visual Basic and Visual C#.

Walkthrough: Authoring a Component with Visual Basic .NET

Components provide reusable code in the form of objects. An application that uses a component's code, by creating objects and calling their properties and methods, is referred to as a *client*. A client may or may not be in the same assembly as a component it uses.

The following procedures build on each other, so the order in which you perform them is important.

Creating the Project

To create the CDemoLib class library and the CDemo component

1. From the **File** menu, select **New** and then **Project** to open the **New Project** dialog. Select the **Class Library** project template from the list of **Visual Basic Projects**, and enter **CDemoLib** in the **Name** box.

   Note The Class Library template is not available in the Standard Edition of Visual Basic .NET. For more information, see Visual Basic Standard Edition Features.

   Tip Always specify the name of a new project when you create it. Doing so sets the root namespace, assembly name, and project name, and also ensures that the default component will be in the correct namespace.

2. In Solution Explorer, right-click **CDemoLib** and select **Properties** from the shortcut menu. Notice that the **Root Namespace** box contains **CDemoLib**.

   The root namespace is used to qualify the names of components in the assembly. For example, if two assemblies provide components named CDemo, you can specify your CDemo component using `CDemoLib.CDemo`.

   Click **Cancel** to close the dialog box.

3. From the **Project** menu, choose **Add Component**. In the **Add New Item** Dialog Box, select **Component Class** and type **CDemo.vb**. in the **Name** box. A component named CDemo.vb is added to your class library.
4. In the Solution Explorer, right-click **CDemo.vb** and choose View code. The code editor opens.

   Notice the `Inherits System.ComponentModel.Component` immediately below `Public Class CDemo`. This section designates the class from which your class inherits. By default, a component inherits from the **Component** class provided by the system. The **Component** class provides many features for your component, including the ability to use designers.

5. In Solution Explorer, right-click **Class1.vb** and choose **Delete**. This deletes the default class that is provided with the class library, as it will not be used in this walkthrough.
6. From the **File** menu, choose **Save All** to save the project.

Adding Constructors and Finalizers

Constructors control the way your component is initialized; the **Finalize** method controls the way it tears down. Code in the constructor and the **Finalize** method of the CDemo class maintains a running count of the number of CDemo objects in existence.

To add code for the constructor and finalizer of the CDemo class

1. In the Code Editor, add member variables to keep a running total of instances of the CDemo class, and an ID number for each instance.

   ```
   Public ReadOnly InstanceID As Integer
   Private Shared NextInstanceID As Integer = 0
   Private Shared ClassInstanceCount As Long = 0
   ```

   Because the `InstanceCount` and `NextInstanceID` member variables are declared **Shared**, they exist only at the class level. All instances of CDemo that access these members will use the same memory locations. Shared members will be initialized the first time the CDemo class is referred to in code. This could be the first time a CDemo object is created, or the first time one of the class' shared members is accessed.

2. Locate **Public Sub New()** and **Public Sub New(Container As System.ComponentModel.IContainer)**, the default constructors for the CDemo class. In Visual Basic .NET, all constructors are named **New**. Your component can have several constructors, with different parameters, but they must all have the name **New**.

Note The access level of a class' constructors determines what clients will be able to create instances of the class. In other versions of Visual Basic, object creation was controlled by the Instancing property; if you've used the **Instancing** property, you may find it useful to read Component Instancing Changes in Visual Basic.

3. Add the following code to **Sub New()**, to increment the instance count when a new CDemo is created, and to set the instance ID number. You may have to expand the **Component Designer Generated Code** box in the code editor.

   Note Always add your code after the call to **InitializeComponent**. At that point, any constituent components have been initialized.

```
InstanceID = NextInstanceID
NextInstanceID += 1
ClassInstanceCount += 1
```

   As a **ReadOnly** member, `InstanceID` can be set only in the constructor.

   Note Users familiar with multithreading will point out quite rightly that assigning
   InstanceID
   and incrementing
   NextInstanceID
   should be an atomic operation. This and other issues related to threading are illustrated in
   Walkthrough: Authoring a Simple Multithreaded Component with Visual Basic

4. Add the following method after the end of the constructor:

```
Protected Overrides Sub Finalize()
   ClassInstanceCount -= 1
   End Sub
```

   The memory manager calls **Finalize** just before it finally reclaims memory occupied by the CDemo object. The **Finalize** method originates with **Object**, the root of all reference types in the .NET class hierarchy. By overriding **Finalize**, you can perform cleanup just before your component is removed from memory. However, as you'll see later in this walkthrough, there are good reasons to release resources earlier.

Adding a Property to the Class

The CDemo class has only one property, a shared property that allows the client to find out how many CDemo objects there are in memory at any given time. Methods can be created in a similar way.

To create a property for the CDemo class

- Add the following property declaration to the CDemo class, to allow clients to retrieve the number of instances of CDemo.

```
Public Shared ReadOnly Property InstanceCount() As Long
   Get
      Return ClassInstanceCount
   End Get
End Property
```

   Note Property declaration syntax is different from that employed in earlier versions of Visual Basic. For more information of the syntax change, see Property Changes in Visual Basic.

Testing the Component

To test the component, you need a project that uses it. This project must be the first project that starts when you press the Run button.

To add the CDemoTest client project as the startup project for the solution

1. From the **File** menu, point to **Add Project** and choose **New Project** to open the **Add New Project** dialog box.
2. Select the **Windows Application** project template from the list of Visual Basic Projects, and type **CDemoTest** in the **Name** box and then click **OK**.

3. In Solution Explorer, right-click **CDemoTest** and click **Set as Startup Project** on the shortcut menu.

In order to use the CDemo component, the client test project must have a reference to the class library project. After adding the reference, it is a good idea to add an **Imports** statement to the test application to simplify use of the component.

To add a reference to the class library project

1. In Solution Explorer, right-click the **References** node immediately beneath **CDemoTest**, and select **Add Reference** from the shortcut menu.
2. In the **Add Reference** dialog box, select the **Projects** tab.
3. Double-click the **CDemoLib** class library project, to add it to the **Selected Components** list. CDemoLib will appear under the References node for the CDemoTest project. Click **OK** to accept the selection.
4. In Solution Explorer, right-click **Form1.vb** and select **View Code** from the shortcut menu.

Adding the reference to CDemoLib allows you to use the fully qualified name of the CDemo component — that is, CDemoLib.CDemo.

To add an Imports statement

- Add the following **Imports** statement to the top of the Code Editor for Form1, above the Class declaration:

  ```
  Imports CDemoLib
  ```

  Adding the **Imports** statement allows you to omit the library name, and refer to the component type as CDemo. For more information on the **Imports** statement, see Namespaces.

  You will now create and use a test program to test your component.

Understanding Object Lifetime

The CDemoTest program will illustrate object lifetime in the .NET Framework by creating and releasing large numbers of CDemo objects.

To add code to create and release CDemo objects

1. Click **Form1.vb[Design]** to return to the designer.
2. Drag a **Button** and a **Timer** from the **Windows Forms** tab of the Toolbox onto the Form1 design surface.

   The nonvisual **Timer** component appears on a separate design surface below the form.

3. Double-click the icon for **Timer1** to create an event-handling method for the Timer1 component's **Tick** event. Place the following code in the event-handling method.

   ```
   Me.Text = "CDemo instances: " & CDemo.InstanceCount
   ```

   On every tick of the timer, the form's caption will display the current instance count for the CDemo class. The class name is used as a qualifier for the shared InstanceCount property — there is no need to create an instance of CDemo to access a shared member.

4. Locate the constructor for Form1 (**Sub New**), and add the following code after the call to **InitializeComponent**.

   ```
   Timer1.Enabled = True
   ```

   This will start the timer as soon as the form is created.

5. Click the **Form1.vb [Design]** tab to return to the designer.
6. Double-click the **Button** on Form1, to create an event-handling method for the button's **Click** event. Place the following code in the event-handling method.

   ```
   Dim cd As CDemo
   Dim ct As Integer
   For ct = 1 To 1000
      cd = New CDemo
   Next
   ```

This code may look strange to you. As each instance of CDemo is created, the previous instance is released. When the **For** loop is done, there will be only one instance of CDemo left. When the event-handling method exits, even that instance will be released, because the variable `cd` will go out of scope.

As you may have guessed already, things won't happen quite that way.

To run and debug the CDemoTest and CDemo projects

1. Press **F5** to start the solution.

   The client project will start, and Form1 will be displayed. Notice that the caption of the form displays "CDemo instances: 0".

2. Click the button. The caption of the form should display "CDemo instances: 1000".

   The instances of CDemo were all released by the time the button's **Click** event-handling procedure finished. Why haven't they been finalized? In brief, the memory manager finalizes objects in the background, at low priority. The priority is only bumped up if the system gets low on memory. This "lazy" garbage collection scheme allows for very fast object allocation.

3. Click the button several more times, watching the caption. At some point, the number of instances will suddenly drop. This means that the memory manager has reclaimed the memory of some of the objects.

   > **Note** If you've clicked more than 10 times, and the number of CDemo instances has not decreased, you may need to adjust the code so that it uses more memory. Close the form to return to the development environment, and increase the number of iterations in the **For** loop to 10000. Then run the project again.

4. Repeat step 3. You will get farther this time before the memory manager finalizes more objects.

   In fact, each time you repeat step 3, you will probably be able to allocate more CDemo objects before the memory manager steps in. This is because more and more of Visual Studio is swapped out, leaving more space for instances of CDemo.

5. Close the form to return to the development environment.

Programming with Components | Component Authoring Walkthroughs

Walkthrough: Authoring a Component with Visual C#

Components provide reusable code in the form of objects. An application that uses a component's code, by creating objects and calling their properties and methods, is referred to as a *client*. A client may or may not be in the same assembly as a component it uses.

The following procedures build on each other, so the order in which you perform them is important.

Creating the Project

To create the CDemoLib class library and the CDemo component

1. From the **File** menu, select **New** and then **Project** to open the **New Project** dialog. Select the **Class Library** project template from the list of **C# Projects**, and enter **CDemoLib** in the **Name** box.

   Tip Always specify the name of a new project when you create it. Doing so sets the root namespace, assembly name, and project name, and also ensures that the default component will be in the correct namespace.

2. In Solution Explorer, right-click **CDemoLib** and select **Properties** from the shortcut menu. Notice that the **Root Namespace** box contains **CDemoLib**.

   The root namespace is used to qualify the names of components in the assembly. For example, if two assemblies provide components named CDemo, you can specify your CDemo component using `CDemoLib.CDemo`.

   Click **Cancel** to close the dialog box.

3. From the **Project** menu, choose **Add Component**.
4. In the **Add New Item** dialog box, select **Component Class** and type **CDemo.cs**. in the **Name** box.

   A component named CDemo.cs is added to your class library.

5. In Solution Explorer, right-click **CDemo.cs** and choose View code. The code editor opens.

   Notice the `: System.ComponentModel.Component` immediately after `public class CDemo`. This section designates the class from which your class inherits. By default, a component inherits from the **Component** class provided by the system. The **Component** class provides many features for your component, including the ability to use designers.

6. In Solution Explorer, right-click **Class1.cs** and choose **Delete**. This deletes the default class that is provided with the class library, as it will not be used in this walkthrough.
7. From the **File** menu, choose **Save All** to save the project.

Adding Constructors and Destructors

Constructors control the way your component is initialized; the **Finalize** method controls the way it tears down. Code in the constructor and the **Finalize** method of the CDemo class maintains a running count of the number of CDemo objects in existence.

To add code for the constructor and destructor of the CDemo class

1. In the Code Editor, add member variables to keep a running total of instances of the CDemo class, and an ID number for each instance.

   ```
   public readonly int InstanceID;
   private static int NextInstanceID = 0;
   private static long ClassInstanceCount = 0;
   ```

   Because the `InstanceCount` and `NextInstanceID` member variables are declared **static**, they exist only at the class level. All instances of CDemo that access these members will use the same memory locations. Shared members will be initialized the first time the CDemo class is referred to in code. This could be the first time a CDemo object is created, or the first time one of the class' shared members is accessed.

2. Locate **public CDemo()** and **public CDemo(System.ComponentModel.IContainer container)**, the default constructors for the CDemo class. In Visual C# .NET, all constructors have the same name as the class. Your component can have several constructors, with different parameters, but they must all have the same name as your component.

   Note The access level of a class' constructors determines what clients will be able to create instances of the

class.

3. Add the following code to `public CDemo()`, to increment the instance count when a new CDemo is created, and to set the instance ID number. You may have to expand the **Component Designer Generated Code** box in the Code Editor.

   Note Always add your code after the call to **InitializeComponent**. At that point, any constituent components have been initialized.

```
InstanceID = NextInstanceID ++;
ClassInstanceCount ++;
```

   As a `readonly` member, `InstanceID` can be set only in the constructor.

   Note Users familiar with multithreading will point out quite rightly that assigning
   InstanceID
   and incrementing
   NextInstanceID
   should be an atomic operation. This and other issues related to threading are illustrated in Walkthrough: Authoring a Simple Multithreaded Component with Visual C#.

4. Add the following method after the end of the constructor:

```
~CDemo()
{
   ClassInstanceCount --;
}
```

   This method is called a *destructor*, and is signified by the tilde character (~) in front of the class name. The memory manager calls the destructor just before it finally reclaims memory occupied by the CDemo object. By implementing a destructor you can perform cleanup just before your component is removed from memory. However, as you'll see later in this walkthrough, there are good reasons to release resources earlier.

Adding a Property to the Class

The CDemo class has only one property, a shared property that allows the client to find out how many CDemo objects there are in memory at any given time. Methods can be created in a similar way.

To create a property for the CDemo class

- Add the following property declaration to the CDemo class, to allow clients to retrieve the number of instances of CDemo.

```
public static long InstanceCount
   {
      get
      {
         return ClassInstanceCount;
      }
   }
```

Testing the Component

To test the component, you need a project that uses it. This project must be the first project that starts when you press the Run button.

To add the CDemoTest client project as the startup project for the solution

1. From the **File** menu, point to **Add Project** and choose **New Project** to open the **Add New Project** dialog box.
2. Select the **Windows Application** project template from the list of Visual C# Projects, and type **CDemoTest** in the **Name** box and then click **OK**.
3. In Solution Explorer, right-click **CDemoTest** and click **Set as Startup Project** from the shortcut menu.

In order to use the CDemo component, the client test project must have a reference to the class library project. After adding the

reference, it is a good idea to add a **using** statement to the test application to simplify use of the component.

To add a reference to the class library project

1. In Solution Explorer, right-click the **References** node immediately beneath **CDemoTest**, and select **Add Reference** from the shortcut menu.
2. In the **Add Reference** dialog box, select the **Projects** tab.
3. Double-click the **CDemoLib** class library project, to add it to the **Selected Components** list. CDemoLib will appear under the References node for the CDemoTest project. Click **OK** to accept the selection.
4. In Solution Explorer, right-click **Form1.cs** and select **View Code** from the shortcut menu.

Adding the reference to CDemoLib allows you to use the fully qualified name of the CDemo component — that is, CDemoLib.CDemo.

To add a using statement

- Add the following **using** statement to the list of **using** statements at the top of the Code Editor for Form1.

  ```
  using CDemoLib;
  ```

  Adding the **using** statement allows you to omit the library name, and refer to the component type as CDemo.

  You will now create and use a test program to test your component.

Understanding Object Lifetime

The CDemoTest program will illustrate object lifetime in the .NET Framework by creating and releasing large numbers of CDemo objects.

To add code to create and release CDemo objects

1. Click **Form1.cs[Design]** to return to the designer.
2. Drag a **Button** and a **Timer** from the **Windows Forms** tab of the Toolbox onto the Form1 design surface.

   The nonvisual **Timer** component appears on a separate design surface below the form.

3. Double-click the icon for **timer1** to create an event-handling method for the timer1 component's **Tick** event. Place the following code in the event-handling method.

   ```
   this.Text = "CDemo instances: " + CDemo.InstanceCount;
   ```

   On every tick of the timer, the form's caption will display the current instance count for the CDemo class. The class name is used as a qualifier for the shared InstanceCount property — there is no need to create an instance of CDemo to access a shared member.

4. Locate the constructor for Form1 (**public Form1()**), and add the following code after the call to **InitializeComponent()**.

   ```
   timer1.Enabled = true;
   ```

   This will start the timer as soon as the form is created.

5. Click the **Form1.cs [Design]** tab to return to the designer.
6. Double-click the **Button** on Form1, to create an event-handling method for the button's **Click** event. Place the following code in the event-handling method.

   ```
   CDemo cd;
   int ct;
   for (ct = 0; ct < 1000; ct++)
      cd = new CDemo();
   ```

   This code may look strange to you. As each instance of CDemo is created, the previous instance is released. When the **for** loop is done, there will be only one instance of CDemo left. When the event-handling method exits, even that instance will be released, because the variable `cd` will go out of scope.

As you may have guessed already, things won't happen quite that way.

To run and debug the CDemoTest and CDemo projects

1. Press **F5** to start the solution.

   The client project will start, and Form1 will be displayed. Notice that the caption of the form displays "CDemo instances: 0".

2. Click the button. The caption of the form should display "CDemo instances: 1000".

   The instances of CDemo were all released by the time the button's **Click** event-handling procedure finished. Why haven't they been finalized? In brief, the memory manager finalizes objects in the background, at low priority. The priority is only bumped up if the system gets low on memory. This "lazy" garbage collection scheme allows for very fast object allocation.

3. Click the button several more times, watching the caption. At some point, the number of instances will suddenly drop. This means that the memory manager has reclaimed the memory of some of the objects.

   > **Note** If you've clicked more than 10 times, and the number of CDemo instances has not decreased, you may need to adjust the code so that it uses more memory. Close the form to return to the development environment, and increase the number of iterations in the **for** loop to 10000. Then run the project again.

4. Repeat Step 3. You will get farther this time before the memory manager finalizes more objects.

   In fact, each time you repeat step 3, you will probably be able to allocate more CDemo objects before the memory manager steps in. This is because more and more of Visual Studio is swapped out, leaving more space for instances of CDemo.

5. Close the form to return to the development environment.

Programming with Components | Component Authoring Walkthroughs

Authoring Components

There are as many ways to approach a programming problem as there are programmers, and creating your own components is just another programming task. With that in mind, the following steps represent a fairly comprehensive approach.

To author a component

1. Determine what you want your component to accomplish, or what part it will play in your application.
2. If you have a more complex component and need an object model, outline the model. For more information, see Component Object-Model Recommendations
3. If necessary, divide up functionality between the component and any subobjects or structures in its object model. For more information, see Nested Classes in Components.
4. Determine the best class or component to use as a base class for your component. Generally speaking, your base class will already implement many of the properties and methods that your class will need.
5. If you have subobjects, determine the best class or component to use as a base class for them.
6. Determine what functionality your component can provide by incorporating components from the .NET Framework classes.
7. If you need to factor out subsets of your component's functionality as interfaces, determine which classes need to implement them.
8. Express functionality as properties, methods, and events of the component and its subobjects or subsidiary structures. For more information, see Implementing Properties, Methods, Members, and Events in Components.
9. Assign appropriate access levels (**Public**, **Private**, and so on). For more information, see Ways to Implement Component Functionality.
10. Test and debug your component. As you add each feature, add features to your test project to exercise the new functionality.
11. Repeat, refining the design.

Component Architecture

The topics in this section explain the overall architecture of components for the common language runtime. The .NET Framework is a library of components, plus supporting classes and structures, designed to make component development easy and robust. Components are defined more strictly than in COM: A component either implements the **System.ComponentModel.IComponent** interface, or has the **System.ComponentModel.Component** class somewhere in its inheritance tree.

The common language runtime is a requirement for any application developed with the framework. For information on the organization of classes in the libraries, see Introduction to the .NET Framework Class Library.

Ways to Implement Component Functionality

You will frequently find it useful to create utility functions and small "helper" objects for your components. You can implement such utility objects and functions using classes and structures. Additionally, in Visual Basic you can implement modules.

> **Visual Basic Note** In previous versions of Visual Basic, classes were the only way to expose component functionality. Standard modules were useful receptacles for internal data and utility functions, but could not be exposed outside the project. User-defined types could be exposed, but had no functionality other than providing complex data types. These restrictions have been removed.

Classes have the advantage of being reference types — passing a reference is more efficient than passing a structure variable with all its data. On the other hand, structures do not require allocation of memory on the global heap.

The following table summarizes the differences between the ways of implementing component functionality. In C# the access modifiers (**Public**, for example) are lowercase (**public**).

	Class	**Structure (struct)**	**Module (Visual Basic only)**
Default access level for the type	**Friend/internal**	**Friend/internal**	**Friend**
Default access level for data members	**Private**	**Public** (Visual Basic .NET) **private** (Visual C#)	**Private**
Default access level for properties and methods	**Public** (Visual Basic) **private** (Visual C#)	**Public** (Visual Basic .NET) **Private** (Visual C#)	**Public**
Value or reference type?	Reference	Value	Neither
Can be a base for new types?	Yes	No	No
Can implement interfaces?	Yes	Yes	No
Can raise and handle events?	Yes	Yes	Yes
Scope of members	Class	Structure	Module and containing Namespace
Instance creation?	**New** operator (Visual Basic) constructor (C#)	**New** operator (Visual Basic) constructor (C#)	Not instanced
Type initialization	Shared constructor, shared initializers	Shared constructor, shared initializers	Shared initializer
Instance initialization	Parameterized constructor, parameterless constructor	Parameterized constructor, parameterless constructor	Not instanced
Can contain nested types?	Yes	Yes	Yes
Can be a nested type?	Yes	Yes	No
Destructor?	Yes	No	No

Structures

Structures are value types — that is, a variable of a structure type contains the structure's data, rather than containing a reference to the data as a class type does. Structures can have properties and methods, can raise and handle events, and can implement interfaces.

> **Visual Basic Note** Previous versions of Visual Basic provided a **Type** statement for defining structures. The **Structure** statement adds many new capabilities. For details, see Structure Statement.

- A structure has an implicit parameterless constructor, which initializes each data member of the structure to the default value for its type.

  > **Note** This means that you cannot declare your own parameterless constructor for a structure.

- In addition to its defined members, a structure includes the members of **System.ValueType**.
- Because you cannot inherit from a structure, **Protected** access is prohibited on structure members.
- Unlike a class, a structure does not have a finalizer (**Sub Finalize** in Visual Basic).
- You can use **Public Shared** (**public static** in C#) members to provide utility functions related to a type. **Shared** (**static**)

members can be called using the type name; no instance of the type is required.

> **Visual Basic Note** Data members in structures must be declared with the **Dim** statement, or with **Public**, **Private**, or **Friend**. This is a change from the user-defined types in earlier versions of Visual Basic.

Although a structure can have properties, methods, and shared data, these do not affect the space occupied by a variable of the structure type. The space allocated for a structure is only as large as the structure's instance data.

When Should You Use a Structure Instead of a Class?

Because you cannot inherit from a structure, structures should be used only for objects that do not need to be extended. Use structures when the object you wish to create has a small instance size, and take into account the performance characteristics of classes versus structures. In general, objects requiring a larger instance size should be created as a class. Structures with large instance sizes cause degradation in performance as the instance data is passed from method to method. Depending on how the structure is allocated and used, however, a structure may be more efficient even with a larger instance size. For example, a structure allocated and passed around inside an array can be efficient.

Classes

In addition to providing all the capabilities of structures, classes can be extended and they have finalizers.

Classes Can Be Extended

By default, your component can be a base class for new components. If you do not want to invest the additional development and testing time to ensure that your component can function as a robust base class, you can mark your class **NotInheritable** (Visual Basic) or **sealed** (C#) to prevent users from extending its functionality.

You can also author a component whose sole purpose is to be a base class for other components, by marking it **MustInherit** (Visual Basic) or **abstract** (C#). Users of your assembly cannot create instances of an **abstract** (**MustInherit)** class; they must derive new component classes from it. For details, see Abstract Classes.

> **Note** When you include an abstract component in your assembly, or any component you intend users to inherit from, you should provide documentation for your component.

Destructors

Before garbage collection frees the memory used by an object, the class finalizer is called. This gives you the opportunity to do any necessary cleanup. However, because of the indeterminate nature of garbage collection, you have no way of knowing when your finalizer will be called. If you want to be able to control when your component terminates, you should implement a **Dispose** method for it. For details, see Initialization and Termination of Components.

Importing Shared Class Members (Visual Basic Only)

Users can import the **Public Shared** members of a class so that they can be accessed without qualification. The following example makes the public shared members of the Mortgage class available without qualification.

```
' Visual Basic
Imports MyCorp.Financials.Mortgage
```

Modules (Visual Basic Only)

Modules provide a simple way to organize utility functions and global data used by the components in your assembly.

- A member of a module can be accessed without qualification within the namespace that contains the definition of the module and within any file that has imported that namespace. If members with duplicate names exist in two modules, you can qualify them with the module names to resolve the ambiguity.
- A module must be a member of a namespace. It cannot be a member of another type, such as a class.
- Modules are not instanced and are functionally equivalent to classes containing only shared members.
- A module cannot have an instance constructor.

If a module is declared **Public**, its public members are visible outside your assembly. In order to access these members, a user of your assembly must qualify them with the name of the module.

Walkthrough: Authoring a Component with Visual Basic .NET | Component Architecture

Components and Assemblies

Components are packaged in *assemblies*. Assemblies are the reusable, versionable, self-describing building blocks of .NET applications. The simplest assembly is a single executable that contains all the information necessary for deployment and versioning.

The metadata describing an assembly is called the *manifest*. In the most general case, an assembly can consist of a number of executable files and resource files. In that case, the manifest may be a separate file, or it may be included in one of the executable files. Assemblies enable the common language runtime to locate and securely execute code. In particular, the runtime uses assemblies for the following purposes:

- Establishing security and version identity for code.
- Providing a scope for class and type resolution.
- Locating classes to load.

Assemblies and Versioning

One of the primary goals of assemblies is versioning. Specifically, assemblies provide a means for developers to specify version rules between different software components, and to have those rules enforced at run time.

Because assemblies are the building blocks of applications, they are the logical point for specifying and enforcing version information. Each assembly has a specific version number as part of its identity.

The version number is stored in the assembly's manifest along with other identity information, including the friendly name and supported locales. The fact that a version number is part of an assembly's identity is the key to versioning: AssemblyA, version 1 and AssemblyA, version 2 are two completely different entities, and are treated as such at run time.

For more general information on assemblies, see Assemblies in the .NET Framework documentation.

Component Architecture | Assemblies

Reference Counting, Garbage Collection, and Object Lifetime

Unlike COM, the common language runtime does not use reference counting to govern object lifetime. Instead, the garbage collector traces object references and identifies objects that can no longer be accessed by running code.

This simplifies component programming a great deal, because you do not have to worry about circular references. If a group of objects contain references to each other, but none of these object are referenced directly or indirectly from stack or shared variables, then garbage collection will automatically reclaim the memory.

An additional advantage of traced garbage collection is that allocation of new objects in memory is extremely fast. Performance is further improved by the elimination of the COM **AddRef** and **Release** mechanism, and objects require less memory.

The only potential disadvantage of traced garbage collection is the interval between the release of the last reference that can be reached by running code, and the moment when the garbage collector detects this condition. On a lightly loaded system with a great deal of memory, considerable time may elapse before your component's destructor is called.

The technique used in the .NET Framework is to implement a **Dispose** method on any component that uses limited or expensive system resources. When you are done using an instance of your component, you can call **Dispose** to free all resources except the memory the component is occupying, and to disable the component. For details, see Initialization and Termination of Components.

Component Architecture | Component.Dispose Method | IDisposable Interface

Component Naming Recommendations

The names you select for your classes — and for their properties, methods, and events — are one of the most important factors in how easy it is to use your component. When naming these elements and their formal parameters, you can help the user of your component by following a few simple rules.

- Use complete words whenever possible — for example, SpellCheck. Abbreviations can take many forms, and hence can be confusing. If you plan to localize your component for other cultures, be aware that abbreviations can be hard for a non-native speaker to understand. If whole words are too long, use complete first syllables or carefully chosen abbreviations.
- Use mixed case for your class, method, and property names, capitalizing each word or syllable — for example, ShortcutMenus, or AsyncReadComplete.
- Use the same word or phrase your users would use to describe a concept. For example, you might have a SavingsAccount component that represented a savings account.
- Append "Collection" onto the correct name of the object contained by your collection — for example WorksheetCollection, FormCollection, or WidgetCollection.
- Use either the verb/object or object/verb order consistently for your method names. For example, placing the verb first results in names like InsertWidget and InsertSprocket, whereas placing the object first yields names like WidgetInsert and SprocketInsert.
- Do not repeat the name of the class in the method. For example, if you have a class named Book, do not have a method called Book.CloseBook. Instead, name your method Book.Close.

Coding Techniques

Component Classes

A class is a unit of reusable code. So is a component. To author a component, you start with a class. What is the difference, then?

A class becomes a component when it conforms to a standard for component interaction. This standard is provided through the **IComponent** interface. Any class that implements the **IComponent** interface is a component. For details about interfaces, see Polymorphism in Components. Such standards allow developers to plug components together quickly to create larger programs. The common language specification (CLS) describes the way components authored for the common language runtime can interact. For details, see What Is the Common Language Specification?

The .NET Framework provides the **IComponent** interface and the **Component** base class to make it easy to author components that work well in the design environment, and **UserControl** and **Control** classes that make it easy to author visual components.

Component Class Characteristics

The characteristics of a class acquire additional significance when the class becomes a component.

Component Name

Choose component class names carefully. A class name should be short but descriptive, formed from whole words, with individual words capitalized — for example, BusinessRule. This provides a convenient way to organize your components and to produce shorthand clues to component functions. For more information, see Component Naming Recommendations.

Access Modifier

A class defined with private access is not visible to users of your assembly. This is the access level to use for helper classes internal to the assembly.

Setting the **Access** modifier to public makes a component class available to users of your assembly. To control whether users of your assembly can create instances of the component, specify the appropriate access level for its constructor. For details, see Component Instancing and Constructors.

Base Class

Unless you intend to implement the **IComponent** interface yourself, your base class should be **System.ComponentModel.Component** or a class that derives from **System.ComponentModel.Component**. You can find this information in the reference topic for any class in the .NET Framework. In Visual Basic, the **Inherits** statement specifies the base class. In C#, the base class follows the colon in the class declaration. Examples are shown below:

```
' Visual Basic
Imports System.ComponentModel
Public Class MyComponent
   Inherits System.ComponentModel.Component
End Class

//C#
using System.ComponentModel
public class MyComponent:System.ComponentModel.Component;
{}
```

Namespace Statement

Every component is contained within a *namespace*. By default, the namespace is the name of your project. Users of your component assembly will add **Imports** (Visual Basic) or **using** (C#) statements for the namespaces containing components they want to access.

> **Note** You can add additional levels of structure by enclosing components within additional **Namespace...End Namespace** blocks.

Generally speaking, the structure of namespaces in your component assembly should reflect its internal organization. If your assembly contains a large number of components, it makes sense to group related components in separate namespaces.

Walkthrough: Authoring a Component with Visual Basic .NET | Initialization and Termination of Components | Component Instancing and Constructors | Component Instancing Changes in Visual Basic | Components and Assemblies

Initialization and Termination of Components

Your component is initialized by its constructor (**Sub New** in Visual Basic) and destroyed by its destructor (**Sub Finalize** in Visual Basic). Your component's constructor is called when an instance of your component is created; the constructor cannot be called thereafter. The destructor is called just before your component is destroyed by garbage collection and its memory is reclaimed.

> **Visual Basic Note** In previous versions of Visual Basic, the **Initialize** and **Terminate** events served the same purpose as the constructor and destructor.

Waiting for Garbage Collection

The common language runtime calls your component's destructor after the garbage collection determines that the component can no longer be reached by any executing code. This happens if all references to the component have been released, or if the only references to your component are held by objects that are similarly isolated from all executing code — for example, in the case of circular references.

Because there can be a delay between the moment when a user is finished with your component and the moment when its destructor is called, an additional step is introduced into the lifetime of .NET components: If your component acquires system resources, such as database connections or handles to Windows system objects, you should implement the **IDisposable** interface, and provide a **Dispose** method so that users of your component can choose when to release those resources.

Life Cycle of a Component

1. **Type initialization**: When the first instance of your component is created, the first code that executes is any shared initialization code. A reference to any shared member will also cause the shared constructor to execute. This includes any shared fields (member variables) that are initialized, and the shared constructor (**Shared Sub New**) if it exists. In the following code, a reference font is created for the entire class.

   > **Note** The C# keyword that corresponds to **Shared** is **static**, which is not to be confused with the **Static** keyword in Visual Basic.

   ```
   ' Visual Basic
   Public Class ADrawing
   Shared ReadOnly ReferenceFont As New Font("TimesNewRoman", 14)
   ' Shared constructor does not overload other constructors.
   Shared Sub New()
      ' There is no call to the base class's shared constructor.
      ' Insert code to initialize the shared data.
   End Sub
   End Class

   // C#
   class ADrawing
   {
      static Font m_referenceFont = new Font("TimesNewRoman", 14);
      // Simply add the static keyword to create a static constructor.
      // Static constructors do not have any parameters.
      static ADrawing()
      {
         // There is no call to the base class's static constructor.
         // Code to initialize the font here.
      }
   }
   ```

   > **Note** Class initialization can occur even if no instances of your component are created. For example, an **abstract** (**MustInherit**) class with shared member functions will be initialized and those functions will be available for use by the application, even though no instance of the class is created.

2. **Instance initialization**: When an instance of your component is created, data members that have initialization code are initialized, and the appropriate constructor overload is executed. The following code initializes a private field and defines two

constructors, one to be called if there are no parameters, and the other to be called if the user specifies parameters.

```
' Visual Basic
Class AShape
   Private answer As Integer = 42
   Public Sub New()
      ' Call another constructor with default initialization values.
      MyClass.New(System.Drawing.Color.Red, 5280, DefinedSizes.Large)
   End Sub
   Public Overloads Sub New(myColor As Color, myLength As Integer, _
            Size As DefinedSizes)
      ' Insert code to initialize the class.
   End Sub
   ' Defines the DefinedSizes enum
   Public Enum DefinedSizes
      Large
      Small
   End Enum
End Class

// C#
class AShape
{
   private int m_answer = 42;
   // Forward to another constructor.
   public AShape()
   : this(System.Drawing.Color.Red, 5280, DefinedSizes.Large)
   {
      // Additional initialization goes here.
   }

   public AShape(Color color, int length, DefinedSizes size)
   {
      // Code to initialize the class goes here.
   }
   // Defines the DefinedSizes enum
   public enum DefinedSizes
   {
      Large,
      Small
   }
}
```

3. **Disposing of resources**: If your component implements the **IDisposable** interface, it must provide a **Dispose** method, which the client should call when it is finished using the component. Note that any component that inherits from **System.ComponentModel.Component** already has a default implementation of **Dispose**, which can be overridden to provide additional cleanup code. In the **Dispose** method, your component frees all system resources it may have allocated, releases references to other objects, and renders itself unusable. There may also be instances where it is appropriate for your component to call its own **Dispose** method. The following code disposes of a dependent object that has a **Dispose** method.

```
' Visual Basic
' Assumes that the class implements IDisposable
Public Sub Dispose() Implements IDisposable.Dispose
   myWidget.Dispose
   myWidget = Nothing
   ' Insert additional code.
End Sub
```

```
// C#
// Assumes that the class implements IDisposable
public void IDisposable.Dispose()
{
   mywidget.Dispose();
   mywidget = null;
   // Dispose of remaining objects.
}
```

After you call **Dispose**, your client should release any remaining references to the component, so that garbage collection can reclaim the component's memory.

4. **Instance destruction**: When garbage collection detects that there are no remaining references to the component, the runtime calls your component's destructor (**Finalize** in Visual Basic .NET) and frees the memory. You should override your base class's **Finalize** method (for Visual Basic .NET) or implement a destructor (for Visual C#) to implement your own clean-up code, but always include a call to the destructor or **Finalize** method of the base class.

```
' Visual Basic
Protected Overrides Sub Finalize()
   m_Gadget = Nothing
   m_Gear = Nothing
   MyBase.Finalize()
End Sub

// C#
// In C#, a destructor is used instead of a Finalize method.
~ThisClass()
{
   m_gadget = null;
   m_gear = null;
   // The base class finalizer is called automatically
}
```

When Should You Implement a Dispose Method?

If your component inherits from **System.ComponentModel.Component**, a default implementation of **Dispose** is provided. This implementation can be overridden to provide custom cleanup code. If you are building your component by creating a custom implementation of **IComponent**, you should implement **IDisposable** to provide a **Dispose** method for your component.

Your component needs a **Dispose** method if it allocates system objects, database connections, or other scarce resources that should be released as soon as a user is finished with the component.

You should also implement a **Dispose** method if your component holds references to other objects that have **Dispose** methods.

Why Implement Dispose?

Depending on system activity, an unpredictable interval could elapse between the time a user finishes using your component and the time garbage collection detects that the component's code is unreachable. If you do not provide a **Dispose** method, your component will continue to hold its resources during this interval.

A Worst-Case Scenario

Imagine a server component that uses a database connection and does not have a **Dispose** method. On a server with a large amount of memory, you might create and release many instances of the component without having much impact on free memory. In this case, garbage collection might not destroy the components for some time after the references to them are released.

Eventually, all of the available database connections could be tied up by components that had been released but not destroyed. Even though the server had no shortage of memory, it might be unable to respond to user requests.

Component Instancing and Constructors

You can control the way programmers create instances of your component classes. For example, you may want to ensure that every **Book** object is added to the **Library** collection as soon as the user creates it. Or you may want to limit a component to a single instance.

By giving different access levels to your component's constructors (overloads of **Sub New** in Visual Basic), you can control the ways your component is created.

> **Note** If you have used Visual Basic 5.0 or 6.0, you may find it helpful to read Component Instancing Changes in Visual Basic.

Public Constructors

Make a constructor public (**Public Sub New** or **Overloads Public Sub New** in Visual Basic) so that developers can use it to create instances of your component. If you have multiple public constructors, the one that will be invoked is the one that matches the argument list the user specifies.

Friend (Internal) Constructors

If you have a constructor you want to use within your assembly, but do not want to expose to users of your component, use the access level **Friend** (**Friend Sub New** or **Overloads Friend Sub New**) in Visual Basic, or **internal** in C#.

For example, you might want a component to appear only as a member of a collection. If you give its only constructor **Friend** access, users cannot create instances themselves. However, the **Add** method of your collection can use the **New** operator to create an instance of the component, because the component and collection are part of the same assembly. The following sample code illustrates this.

```
' Visual Basic
' Constructor for the Book class.
Class Book
   Friend Sub New(ByVal Ident as Integer, Author as String, Publisher as _
      String)
      ' Insert code to initialize Book object.
   End Sub
End Class
Class Library
   ' Add method for the Books collection class of the Library class.
   Public Function Add(Ident, Author, Publisher) As Book
      Dim b As New Book(Ident, Author, Publisher)
      ' Insert code to insert b into the collection.
      ' Return a reference to the new book.
      Return b
   End Function
End Class

// C#
class Book
{
   // Book class constructor.
   internal Book(int ident, string author, string publisher)
   {
      // Add code to inititialize.
   }
}

class Library
{
   // Add method for the Books collection of the Library class.
   public Book Add(int ident, string author, string publisher)
   {
      Book newBook = new Book(ident, author, publisher);
      // Add code to add newBook to the Books collection.
      // Return a reference to the new book.
      return(newBook);
```

```
    }
}
```

Users of your assembly cannot create the component with the **New** operator because there is no public constructor.

Private Constructors

Make a constructor private if:

- You want it to be available only to the class itself. For example, you might have a special constructor used only in the implementation of your class' **Clone** method.
- You do not want instances of your component to be created. For example, you may have a class containing nothing but **Shared** utility functions, and no instance data. Creating instances of the class would waste memory. In Visual Basic, you would use a module for this kind of construct.

  > **Note** The C# keyword that corresponds to **Shared** is **static**, which is not to be confused with **Static** keyword in Visual Basic.

- You want to limit your component to one instance.

Component Instancing Changes in Visual Basic .NET

In Visual Basic 6.0, instance creation was controlled by the **Instancing** property of a class, which set both the access level (**Public**, **Private**, **Friend**) of a class and the way an object could be created.

In Visual Basic .NET, you set the access modifier for a class to **Public**, **Private**, or **Friend**, and then specify the user's ability to create instances of the class by setting the access level of the constructor (**Sub New**), as shown in the following table.

Visual Basic 6.0 Instancing	Visual Basic .NET
Private	Class **Access** attribute: **Private**
PublicNotCreatable	Class **Access** attribute: **Public** Declare the constructor **Friend** (**Friend Sub New**)
SingleUse	Not supported*
GlobalSingleUse	Not supported*
MultiUse	Class **Access** attribute: **Public** Declare the constructor **Public** (**Public Sub New**)
GlobalMultiUse	Not supported*

* There is no combination of class access and constructor access that duplicates **SingleUse**, **GlobalSingleUse**, or **GlobalMultiUse**. You can get an effect similar to **GlobalMultiUse** by importing a class into a client program, although this only makes shared members accessible without qualification. Public modules also allow a similar effect.

Implementing Properties, Methods, Members, and Events in Components

Your component provides functionality through its properties, methods, and events. Methods are the actions a user can tell your component to execute. Properties and member variables are data a user of your component can get and/or set. Events are notifications that something interesting has happened to your component.

The following topics examine the issues you should be aware of when declaring properties, methods, events, and other members in a component.

In This Section

Method Implementation in Components
Provides conceptual information on implementing methods in your component and overloading methods.
Event Implementation for Components and Custom Controls with Visual Basic
Introduces declaring and raising events.
Troubleshooting Inherited Event Handlers in Visual Basic .NET
Describes how to correct common problems that arise with event handlers in inherited components.
Named Constants for Your Components
Discusses enumerations, read-only constants, and reference-value constants.
Property Implementation in Components
Details custom properties in components.
Default Properties for Your Components
Discusses how default properties and indexers can be used in components.
Exposing Properties of Contained Objects
Describes how to make available a property of a privately contained object in your component.
Saving the Properties of Components
Describes how to serialize and deserialize the properties of your component.

Method Implementation in Components

Methods are blocks of code that are implemented in your component to provide functionality to the user. They provide the functionality that lets your component accomplish specific tasks. Methods are of two types: value-returning and non–value-returning.

In Visual Basic, if a method is required to return a value, it is implemented as a **Public Function** procedure. If no value is returned, it is implemented as a **Public Sub** procedure. Methods are declared using the following syntax:

```
' Visual Basic
Public Function ConvertMatterToEnergy(matter as Integer) As Integer
   Dim energy As Integer
   ' Insert code to convert matter to energy.
   Return energy
End Function
```

Because functions return a value, they must specify a return type, such as **Integer**, **String**, **Object**, and so on The arguments **Function** or **Sub** procedures take, if any, must also be specified.

C# makes no distinction between functions and sub procedures, as Visual Basic does. The method declaration indicates the type of the return value. The **void** keyword is used if the method does not return a value. The syntax for declaring a C# public method is:

```
// C#
public int ConvertMatterToEnergy(int matter)
{
   int energy;
   // Insert code to convert matter to energy.
   return energy;
}
```

When you declare a method, declare all of its arguments as explicit data types whenever possible. Arguments that take object references should be declared as specific class types — for example, **As Widget** instead of **As Object**. For C#, use **widget w** instead of **object w**.

Typed arguments allow many errors to be caught when compiled. The compiler always catches errors, whereas run-time testing is only as good as the coverage of the test suite.

Overloaded Methods

If you want to allow users of your component to supply different combinations of parameters to a method, provide multiple overloads of the method, using explicit data types. Do not create parameters declared **As Object** that can contain any data type.

> **Visual Basic Note** The universal data type in the common language specification is **Object** rather than **Variant**. **Variant** has been removed from the language. For more information, see Universal Data Type Changes in Visual Basic.

For example, the Spin method of a hypothetical Widget object might allow either direct specification of spin direction and speed, or specification of another Widget object from which angular momentum is to be absorbed.

```
' Visual Basic
Overloads Public Sub Spin( _
   ByVal spinDirection As SpinDirectionsEnum, _
   ByVal revolutionsPerSecond As Double)
   ' Insert code to implement the method.
End Sub
Overloads Public Sub Spin(ByVal driver As Widget) _
   ' Insert code to implement the method.
End Sub

// C#
public void Spin(SpinDirectionsEnum spinDirection,
double revolutionsPerSecond)
{
   // Insert code to implement the method.
```

```
}

public void Spin(Widget driver)
{
   // Insert code to implement the method.
}
```

Iterative Design

As you implement functionality in your component, it is important to test it in the scenarios where you expect it to be used. Testing often reveals additional overloaded methods that will be needed by users of your component. For example, consider the hypothetical Widget object from the previous section. After testing your Widget object, you might realize that there are situations where you need it to spin, but cannot provide parameters to either of the overloads of the Spin method. You might solve this problem by adding an overload of the Spin method that takes no parameters to be invoked in these cases. Such an example is shown below:

```
' Visual Basic
Overloads Public Sub Spin()
   ' Insert code to overload the method.
End Sub

// C#
public void Spin()
{
   // Insert code to overload the method.
}
```

Event Implementation for Components and Custom Controls with Visual Basic

Events are ways for your control to communicate with the rest of the program. You *raise* an event in code after predetermined conditions are met. For example, if you were authoring a control that provided a password-protected login, you might raise an event after three unsuccessful login attempts. Once an event is raised, it may be *handled* by the hosting form or control, or it may be ignored altogether. An event is handled by a special method called an *event handler*, which is invoked when the event is raised.

Implementation of events in components is essentially the same as implementation of events in custom controls. The difference, however, is that components do not have a user interface. Therefore, they will usually not respond to events that occur through interaction with the user (for example, mouse clicks). More often, components will respond to events raised by other components. Because event implementation is somewhat different between Visual Basic and C#, there are separate topics for each language. If you are using C#, see Events Tutorial

Declaring an Event in Visual Basic

For an event to be raised, it must first be declared. The following example shows how to declare an event:

```
Public Event TooManyUsersLoggedOn(Users as Integer)
```

There now exists an event called TooManyUsersLoggedOn. It passes a single parameter, Users, when it is raised. An event can have multiple parameters, or none, depending on what is required by the author.

Raising an Event in Visual Basic

Once an event has been declared, it can be raised in code. Raising the event causes the event and its parameters to be shuttled to its event handler, whereupon the code in the event handler executes. An event can be raised in the following manner.

```
RaiseEvent TooManyUsersLoggedOn(6)
```

When an event is raised, it must provide the same number and type of parameters as are in its declaration. Parameters can be used by events to carry information between parts of a program that might not be able to communicate otherwise. This is particularly useful in multi-threaded applications where parameters are the best means of passing methods between threads. For more information, see Walkthrough: Authoring a Simple Multithreaded Component with Visual Basic.

Handling an Event in Visual Basic

After an event is raised, one of two things can occur:

- If there is no handler for the event, it is ignored, and program execution proceeds normally.
- If there is a handler for the event, the code within that method executes and the program proceeds from there.

There are two ways to add an event handler:

- Using the **Handles** keyword and **WithEvents**
- Using the **AddHandler** keyword

The Handles Keyword

The first way to add an event handler is by using the **Handles** keyword as shown:

```
Public Sub RemoveAUser(ByVal Users as Integer) Handles _
   Mycontrol.TooManyUsersLoggedOn
' Insert implementation here
End Sub
```

Using this syntax, the method RemoveAUser will be invoked whenever the TooManyUsersLoggedOn event of MyControl is raised. After this method completes, the program execution will return to the line after where the event was raised. Note that in order to add an event handler in this manner, the control where the event originates must be declared using the keyword **WithEvents**, as shown in the following example:

```
Private WithEvents MyControl as MyUserControl
```

Dynamic Event Handlers with the AddHandler Keyword

A second method of adding an event handler, which does not require the **WithEvents** keyword, is to add the event handler dynamically using the **AddHandler** keyword. Using this method, handlers may be created or removed at run time in accordance with the needs of the program. The **AddHandler** keyword is used as follows:

```
AddHandler MyControl.TooManyUsersLoggedOn, AddressOf RemoveAUser
```

This line dynamically creates a handler for the TooManyUsersLoggedOn event of MyControl. The **AddressOf** keyword creates a delegate that points to the method RemoveAUser, and directs the event to that method. Note that a method added as a handler in this way must take the same number and type of parameters as the event passes.

A handler may also be removed dynamically, using the **RemoveHandler** keyword and similar syntax, as shown:

```
RemoveHandler MyControl.TooManyUsersLoggedOn, AddressOf RemoveAUser
```

Troubleshooting Inherited Event Handlers in Visual Basic .NET

This topic lists common issues that arise with event handlers in inherited components. For more information, see Overriding Event Handlers with Visual Basic .NET.

Code in Event Handler Executes Twice for Every Call

- An inherited event handler must not include a Handles clause. The method in the base class is already associated with the event and will fire accordingly. Remove the **Handles** clause from the inherited method.

```
' INCORRECT
Protected Overrides Sub Button1_Click(ByVal sender As System.Object, _
   ByVal e as System.EventArgs) Handles Button1.Click
   ' The Handles clause will cause all code
   ' in this block to be executed twice.
End Sub

' Visual Basic
Protected Overrides Sub Button1_Click(ByVal sender As System.Object, _
   ByVal e as System.EventArgs)
   ' Insert code to do something here.
End Sub
```

- If the inherited method does not have a **Handles** keyword, verify that your code does not contain an extra AddHandler Statement or any additional methods that handle the same event.

Named Constants for Your Components

Constants provide a convenient way to set and refer to values that are not expected to change. Individual constants may be declared and referred to in code, or sets of related constants may be declared as enumerations.

A constant is declared by using the **Const** keyword (**const** in C#). A constant may represent any intrinsic or enumeration data type (for example, **Integer**, **String**, **Decimal**), but may not be a structure or an instance of a class. Constants use the following syntax:

```
' Visual Basic
Public Const SpeedOfLightInKMPerSecond as Integer = 300000
Private Const ColorOfTheSky as String = "Blue"
Const DensityOfWater as Integer = 1

//C#
public const int SpeedOfLightInKMPerSecond = 300000;
private const string ColorOfTheSky = "Blue";
const int DensityOfWater = 1;
```

Constants and enumerations follow the same access rules as variables. A class-level constant or enumeration may be modified using the same access modifiers (for example, **Public**) as a variable. A procedure-level constant is visible only within the context of the procedure. Enumerations cannot be declared at the procedure level, and must be declared at the class or namespace level. Public constants are not recommended due to the possibility of name confusion. If you wish to have global constants, it is best to use an enum.

Enumerations

Enumerations allow you to define a set of related constants. For instance, you might create an enumeration for the days of the week, as in the following example:

```
' Visual Basic
Public Enum DaysOfTheWeek
   mydaySaturday = 1
   mydaySunday = 2
   mydayMonday = 3
   mydayTuesday = 4
   mydayWednesday = 5
   mydayThursday = 6
   mydayFriday = 7
End Enum

 //C#
public enum DaysOfTheWeek
{
   mydaySaturday = 1,
   mydaySunday = 2,
   mydayMonday = 3,
   mydayTuesday = 4,
   mydayWednesday = 5,
   mydayThursday = 6,
   mydayFriday = 7
}
```

The members of an enumeration need not be sequential. Thus, if you have some general-purpose numeric constants you wish to define for your component, you can put them into a general enum.

```
' Visual Basic
Private Enum General
   genFeetInAMile = 5280
   genIgnitionTemp = 451
End Enum

// C#
private enum General
```

```
{
   genFeetInAMile = 5280,
   genIgnitionTemp = 451,
}
```

Data Types for Enumerations

The default data type for enumerations in Visual Basic is **Integer**, but they may be either **Byte**, **Short**, **Integer**, or **Long**. In C#, it can be any of the integral types except **char**. The default is **int**. If you wish to provide constants of a data type other than those supported in enumerations (such as strings, decimals, and so on), you should do so by using the **Const** (**const** in C#) keyword.

To declare an enumeration as a variable type other than integer, use the following syntax:

```
' Visual Basic
Enum AccountType as Byte
   myAccountSavings = 1
   myAccountChecking = 2
End Enum

// C#
enum AccountType : byte
{
   myAccountSavings = 1,
   myAccountChecking = 2
}
```

See Also

Constants and Enumerations | Enum Statement | const | enum

Property Implementation in Components

Properties allow your component to store, manipulate, and retain data that it requires to run. They are similar to member variables, in that they provide storage for data, but properties are much more robust. Properties are accessed by special methods; the **Get** and **Set** accessors, which allow property values to be validated, additional code to be executed, or other tasks to be performed when the property is set or retrieved. The following example shows a hypothetical property that includes validation code:

```
' Visual Basic
' This is the private member variable that stores the value for the
' property.
Private pMyProperty as Integer
' This is the property block.
Public Property MyProperty() as Integer
   Get
      'Returns the value if pMyProperty.
      Return pMyProperty
   End Get
   Set (Value As Integer)
      ' Checks if a valid value is being assigned to the property.
      If Value > 5 Then
         Messagebox.Show( _
            "Invalid value for the property. Please try again")
      Else
         pMyProperty = Value
      End If
   End Set
End Property

// C#
// This is the private member variable that stores the value for the
// property.
int m_MyProperty;

// This is the property block.
public int MyProperty
{
   // Returns the value of m_MyProperty.
   get
   {
      return m_MyProperty;
   }

   set
   {
      // Checks if a valid value is being
      // assigned to the property.
      if (value > 5)
      {
         MessageBox.Show(
         "Invalid value for the property. Please try again");
      }
      else
      {
         m_MyProperty = value;
      }
   }
}
```

Read-Only Properties

Properties are by default read-write, meaning the values stored in them can be both retrieved and set. Occasionally, you may wish to create a property that cannot be set, but can only be retrieved. These are called *read-only properties*. Read-only properties do not have a **Set** accessor, and their values cannot be changed during run time. An example of a read-only property is shown below: (In C#, a read-only property is created by defining only the **get** method.)

```
' Visual Basic
' This member variable will hold the value of the property.
Private ReadOnly pLength as Integer
Public ReadOnly Property Length() as Integer
   Get
      Return pLength
   End Get
End Property

// C#
// This member variable will hold the value of the property.
private int pLength;

public int Length
{
   get
   {
      return pLength;
   }
}
```

The value of a read-only variable (`pLength` in the above example) can only be set in the constructor of the component or when the member variable is initialized.

Write-Only Properties

Under rare circumstances, you may wish to create a property that can only be set, but the value cannot be retrieved. You might do this in a component that alters global properties in response to an internationalization value, for example. In such a component, different methods would be executed based on the value to which the property is set. These *write-only properties*, as they are called, do not contain a **Get** accessor, and cannot be read during execution of the program. An example is shown below:

```
Private pLanguage as myenumLanguage
Public WriteOnly Property Language() as myenumLanguage
   Set (Value As myenumLanguage)
      pLanguage = Value
      Select Case Value
         Case myenumLanguage.English
            ' Code to implement English.
         Case myenumLanguage.Icelandic
            ' Code to implement Icelandic.
         Case myenumLanguage.Tagalog
            ' Code to implement Tagalog.
      End Select
   End Set
End Property

// C#
myenumLanguage m_language;
public myenumLanguage Language
{
   set
   {
      m_language = value;
      switch (value)
      {
         case myenumLanguage.English :
            // Code to implement English.
            break;
         case myenumLanguage.Icelandic :
            // Code to implement Icelandic.
            break;
         case myenumLanguage.Tagalog :
            // Code to implement Tagalog.
            break;
         default :
            break;
```

```
        }
    }
}
```

The preceding example creates a write-only property that executes different sets of code based upon the value of a property when it is written. There is no way to retrieve the property once it is set, and unless you have a specific reason for making the value of the property inaccessible, it is recommended that you use a read-write property for these constructions.

Default Properties for Your Components

You might want to implement a default property for your component. If you mark a property as the default property of your component, the property name can be omitted in both Visual Basic and C# code. That is, the following lines are equivalent.

```
' Visual Basic
System.Diagnostics.Debug.WriteLine(myWidgets(3).Status)
System.Diagnostics.Debug.WriteLine(myWidgets.Item(3).Status)
```

You can create default properties that accept parameters (such as the **Item** property of a collection), but cannot create a default property that does not accept parameters.

> **Visual Basic Note** In previous versions of Visual Basic, you were allowed to implement parameterless default properties. This is no longer allowed. For details, see Default Property Changes in Visual Basic

The C# equivalent of a default **Item** property is an *indexer*. A C# indexer appears to a Visual Basic programmer as a default Item property, and a Visual Basic default property appears to a C# programmer as an indexer. The following line shows the usage of the indexer for the myWidgets object.

```
// C#
System.Diagnostics.Debug.WriteLine(myWidgets[1].Status);
```

Enabling this shortcut makes sense only if the primary purpose of a component is to contain other objects. Examples of a default property (Visual Basic) and an indexer (C#) are shown below.

```
' Visual Basic
' A class that contains many Widgets
Public Class Widgets
   'Default property implementation
   Default Public Property Widget(ByVal I As Integer) As Widget
      Get
      ' Implementation code to return a widget goes here.
      End Get
      Set(ByVal Value As Widget)
      ' Implementation code to set a widget goes here.
      End Set
   End Property
End Class

// C#
// Class that contains many Widgets.
public class Widgets
{
   // Indexer implementation.
   public Widget this[int index]
   {
      get
      {
         // Insert code to return a Widget.
      }
      set
      {
         // Insert code to set a Widget.
      }
   }
}
// Insert client code.
```

Default Property Changes in Visual Basic | Implementing Properties, Methods, Members, and Events in Components

Exposing Properties of Contained Objects

Your component can act as a container for other objects, such as other components or controls. This means that the container logically encloses a contained object, and the container serves as an additional layer of functionality between the contained object and the client code. An example of this relationship might be a form and a control, where the control is contained in the form. In Visual Studio designers, a contained object is by default private, and thus cannot be accessed by the developer. If you want to make properties of these contained objects available to users of your component, you must expose the properties. A property of a contained object is exposed by creating a property in the container, and using the **Get** and **Set** accessors of that property to effect the change in the private property of the contained object.

Consider a hypothetical component with a contained object named MyComponent. In this example, when the user requests the **ContainedText** property, the value stored in the **Text** property of MyComponent is delivered. When the user assigns a value to this property, that value is automatically passed to the **Text** property of MyComponent and the **Set** code will execute, changing the **Text** property of MyComponent.

The following example shows how to expose the **Text** property of the contained object:

```
' Visual Basic
Public Property ContainedText() as String
   Get
      Return MyComponent.Text
   End Get
   Set(Value as String)
      MyComponent.Text = Value
   End Set
End Property

// C#
public string ContainedText
{
   get
   {
      return MyComponent.Text;
   }
   set
   {
      MyComponent.Text = value;
   }
}
```

To expose a property of a constituent control

1. In the Code Editor for your user control, create a public property. For details, see Property Implementation in Components.
2. In the **Get** section of the property, write code that retrieves the value of the property you want to expose.
3. In the **Set** section of the property, write code that passes the value of the property to the exposed property of the constituent control.

Saving the Properties of Components

Occasionally, you will find it necessary to save the state of your component. You might do this to save personal information about users of your component, or to change the default configuration of a custom control, for example.

You can persist the state of a component to a file through a process called *serialization*. Serialization allows an object to be converted to a stream of data, which can then be saved to a file. The stream can be converted to an object again through deserialization.

The .NET Framework provides two formatters for serialization: The BinaryFormatter Class and SoapFormatter Class. These classes walk an *object graph* (an in-memory representation of your object) currently in memory and convert it to a stream of data. As their respective names imply, the **BinaryFormatter** converts the object graph to a binary stream (which is most useful for desktop applications), and the **SOAPFormatter** converts the object graph to Simple Object Access Protocol (SOAP) format (which is most useful for Internet applications). These streams can then be saved as files that can be deserialized and converted back to objects when needed.

Serializing the Stream

To save the state of your component

1. Apply the SerializableAttribute attribute to the component you want to serialize.

```
' Visual Basic
<Serializable()> Public Class Account
   ' Insert code to implement class.
End Class

// C#
[Serializable()]
public class Account
{
   // ' Insert code to implement class.
}
```

2. Create an instance of this class as the object you want to save.

```
' Visual Basic
Dim myAccount As New Account()

// C#
Account myAccount = new Account();
```

3. Create a **Stream** object as a file to provide a repository for your serialized data.

```
' Visual Basic
Imports System.IO
' This creates a new file with the name SavedAccount.txt, and creates
' a Stream object to write data to that file. The GetFolderPath method
' is used to get the path to the current user's Personal folder.
Dim myFileStream As Stream = File.Create _
   (System.Environment.GetFolderPath _
      (System.Environment.SpecialFolder.Personal))

// C#
using System.IO;
// This creates a new file with the name SavedAccount.txt, and creates
// a Stream object to write data to that file. The GetFolderPath method
// is used to get the path to the current user's Personal folder.
Stream myFileStream = File.Create
   (System.Environment.GetFolderPath
      (System.Environment.SpecialFolder.Personal));
```

4. Create an instance of a formatter class.

   - If you want to convert the object graph to a binary stream, create an instance of the **BinaryFormatter** class.

```
' Visual Basic
Imports System.Runtime.Serialization.Formatters.Binary
Dim serializer As New BinaryFormatter()

// C#
using System.Runtime.Serialization.Formatters.Binary;
BinaryFormatter serializer = new BinaryFormatter();
```

   - If you want to convert the object graph to a SOAP stream, create an instance of the **SoapFormatter** class.

     Note You must have a reference in your project to the **System.Runtime.Serialization.Formatters.Soap** namespace.

```
' Visual Basic
Imports System.Runtime.Serialization.Formatters.Soap
Dim serializer as New SoapFormatter

// C#
using System.Runtime.Serialization.Formatters.Soap;
SoapFormatter serializer = new SoapFormatter();
```

5. Call the **Serialize** method of your formatter to write your object to your **Stream**.

```
' Visual Basic
serializer.Serialize(myFileStream, myAccount)
myFileStream.Close()

// C#
serializer.Serialize(myFileStream, myAccount);
myFileStream.Close();
```

6. Close the file stream to complete serialization.

   You now have a saved instance of your object in binary form in the file SavedAccount.txt.

Deserializing the Stream

After you have saved you object, you will want to retrieve it at some point. The same formatter you used to serialize your component can be used to deserialize it.

To restore a saved component

1. Declare a variable of the same type as the class you want to restore.

```
' Visual Basic
Dim restoredAccount As Account

// C#
Account restoredAccount;
```

2. Create a **Stream** object and open the file that contains the serialized object.

```
' Visual Basic
Imports System.IO
Dim myFileStream As Stream = File.OpenRead _
   (System.Environment.GetFolderPath _
```

```
      (System.Environment.SpecialFolder.Personal))

// C#
using System.IO;
Stream myFileStream = File.OpenRead
   (System.Environment.GetFolderPath
      (System.Environment.SpecialFolder.Personal));
```

3. Create an instance of the same type of formatter class that was used to serialize the data.

   - The following example shows how to use the **BinaryFormatter** class.

```
' Visual Basic
Imports System.Runtime.Serialization.Formatters.Binary
Dim deserializer As New BinaryFormatter()

// C#
using System.Runtime.Serialization.Formatters.Binary;
BinaryFormatter deserializer = new BinaryFormatter();
```

   - The following example shows how to use the **SoapFormatter** class.

     Note You must have a reference to the **System.Runtime.Serialization.Formatters.Soap** namespace already in your project.

```
' Visual Basic
Imports System.Runtime.Serialization.Formatters.Soap
Dim deserializer As New SoapFormatter()

// C#
using System.Runtime.Serialization.Formatters.Soap;
SoapFormatter deserializer = new SoapFormatter();
```

4. Call the **Deserialize** method of your formatter to convert the file stream into an object graph, and use the **CType** function (Visual Basic) or an explicit cast (C#) to convert the object graph into an object of the desired type.

```
' Visual Basic
' The CType function converts the file stream specified in the first
' argument to an object of the type specified in the second argument.
' If the object in the first argument cannot be converted to the
' specified type, an error will result.
restoredAccount = CType(deserializer.Deserialize(myFileStream), _
   Account)
myFileStream.Close()

// C#
// The explicit cast converts the file stream to an object of the type // specified. If t
he object in the file stream cannot be converted to // the specified type, an error will
result.
restoredAccount = (Account)(deserializer.Deserialize(myFileStream));
myFileStream.Close();
```

Security Note You should not use this technique to store any sensitive or secret data, as it is not an acceptable way of securing data. See the System.Security.Cryptography Namespace for information on creating secure encryption schemes for your data.

Interfaces and Abstract Classes

Interfaces and abstract classes allow you to create definitions for component interaction. Through interfaces, you can specify methods that a component must implement without actually specifying how the method is implemented. Abstract classes allow you to create definitions for behavior while providing some common implementation for inheriting classes. Both are valuable tools for implementing polymorphic behavior in your components.

Polymorphism in Components

Polymorphism is the ability for classes to provide different implementations of methods that are called by the same name. Polymorphism allows a method of a class to be called without regard to what specific implementation it provides. For example, you might have a class named Road which calls the Drive method of an additional class. This Car class may be SportsCar, or SmallCar, but both would provide the Drive method. Though the implementation of the Drive method would be different between the classes, the Road class would still be able to call it, and it would provide results that would be usable and interpretable by the Road class.

Polymorphism in components can be implemented in a variety of ways:

- **Interface polymorphism** - Multiple classes may implement the same *interface*, and a single class may implement one or more interfaces. Interfaces are essentially definitions of how a class needs to respond. An interface describes the methods, properties, and events that a class needs to implement, and the type of parameters each member needs to receive and return, but leaves the specific implementation of these members up to the implementing class.
- **Inheritance polymorphism** - Multiple classes may *inherit* from a single base class. By inheriting, a class receives all of the methods, properties, and events of the base class in the same implementation as the base class. Additional members can then be implemented as needed, and base members can be overridden to provide different implementations. Note that an inherited class may also implement interfaces — the techniques are not mutually exclusive.
- **Polymorphism through abstract classes** - Abstract classes provide elements of both inheritance and interfaces. An abstract class is a class that cannot be instantiated itself; it must be inherited. Some or all members of the class might be unimplemented, and it is up to the inheriting class to provide that implementation. Members that are implemented might still be overridden, and the inheriting class can still implement addition interfaces or other functionality.

These three types of polymorphism are discussed in greater detail below.

Interface Polymorphism

A powerful technique in component programming is being able to implement multiple interfaces on an object. Each interface is composed of a small group of closely related methods, properties, and events. By implementing interfaces, your component can provide functionality to any other component requiring that interface, without regard to the particular functionality contained within. This allows successive versions of components to incorporate different capability without disturbing core functionality.

The features of your component most commonly used by other developers should naturally be members of the component class itself. However, components with a large number of members can be difficult to use. Consider factoring out some features of your component as separate interfaces that are implemented privately.

Another benefit of defining features in terms of interfaces is that you can add features to your component incrementally by defining and implementing additional interfaces. Advantages include:

- Design effort is simplified, because components can begin small, with minimal functionality, and continue to provide that functionality while acquiring additional features over time, as it becomes clear from actual use what those features should be.
- Maintaining compatibility is simplified, because new versions of a component can continue to provide existing interfaces, while adding new interfaces. Subsequent versions of client applications can take advantage of these when it makes sense for them to do so.

Polymorphism Through Inheritance

Visual Basic and C# also provide polymorphism through inheritance. This is a powerful mechanism for small-scale development tasks, but has generally proven to be problematic for large-scale systems. An over-emphasis on inheritance-driven polymorphism typically results in a massive shift of resources from coding to designing, which does nothing to shorten overall development time.

Given that the real test of software is whether it works for end users, tools for rapid prototyping and rapid application development (RAD) have gained wider acceptance than tools for object-oriented programming.

When to Use Inheritance-Driven Polymorphism

The foremost use of inheritance is to add functionality to an existing base class. Programmer productivity is much greater when you start with a framework of fully debugged base classes, and methods can be incrementally added to base classes without breaking versioning.

You may also wish to use inheritance when your application design includes several related classes that must share identical implementation for certain common functions. The overlapping functionality can be implemented in a base class, from which the classes used in the application can be derived. An abstract class combines features of both inheritance and implementation, and may be useful when elements of each are needed.

Polymorphism Through Abstract Classes

Abstract classes provide features of both inheritance and interface implementation. An abstract (**MustInherit** in Visual Basic) class is a class that cannot be instantiated, and must be implemented in an inheriting class. It may contain methods and properties that are already implemented, but it may also incorporate unimplemented procedures which must be implemented in the inheriting class. This allows you to provide an invariant level of functionality in some methods of your class, while leaving flexibility options open for other procedures. An additional benefit of abstract classes is that when new versions of your component are required, additional methods may be added to the base class as needed, whereas interfaces must remain invariant.

When to Use Abstract Classes

An abstract class is useful when you need a group of related components to incorporate a set of methods with identical functionality, but also require flexibility in the implementation of other methods. Abstract classes are also valuable when versioning issues are anticipated, because the base class remains flexible and easily modified. For details, see Recommendations for Abstract Classes vs. Interfaces.

See Also

Interface Implementation Examples | Abstract Classes | Recommendations for Abstract Classes vs. Interfaces | Implementing Existing Interfaces | Design Recommendations for Interfaces and Components

Abstract Classes

Abstract classes are closely related to interfaces. They are classes that cannot be instantiated, and are frequently either partially implemented, or not at all implemented. One key difference between abstract classes and interfaces is that a class may implement an unlimited number of interfaces, but may inherit from only one abstract (or any other kind of) class. A class that is derived from an abstract class may still implement interfaces. Abstract classes are useful when creating components because they allow you specify an invariant level of functionality in some methods, but leave the implementation of other methods until a specific implementation of that class is needed. They also version well, because if additional functionality is needed in derived classes, it can be added to the base class without breaking code.

An abstract class is denoted in Visual Basic by the keyword **MustInherit**. In C#, the **abstract** modifier is used. Any methods that are meant to be invariant may be coded into the base class, but any methods that are to be implemented are marked in Visual Basic with the **MustOverride** modifier. In C#, the methods are marked **abstract**. The following example shows an abstract class:

```
' Visual Basic
Public MustInherit Class WashingMachine
   Sub New()
      ' Code to instantiate the class goes here.
   End sub
   Public MustOverride Sub Wash
   Public MustOverride Sub Rinse (loadSize as Integer)
   Public MustOverride Function Spin (speed as Integer) as Long
End Class

// C#
abstract class WashingMachine
{
   public WashingMachine()
   {
      // Code to initialize the class goes here.
   }

   abstract public void Wash();
   abstract public void Rinse(int loadSize);
   abstract public long Spin(int speed);
}
```

In the above example, an abstract class is declared with one implemented method and three unimplemented methods. A class inheriting from this class would have to implement the Wash, Rinse, and Spin methods. The following example shows what the implementation of this class might look like:

```
' Visual Basic
Public Class MyWashingMachine
   Inherits WashingMachine
   Public Overrides Sub Wash()
      ' Wash code goes here
   End Sub
   Public Overrides Sub Rinse (loadSize as Integer)
      ' Rinse code goes here
   End Sub
   Public Overrides Function Spin (speed as Integer) as Long
      ' Spin code goes here
   End Sub
End Class

// C#
class MyWashingMachine : WashingMachine
{
   public MyWashingMachine()
   {
      // Initialization code goes here.
   }

   override public void Wash()
   {
```

```
        // Wash code goes here.
    }

    override public void Rinse(int loadSize)
    {
        // Rinse code goes here.
    }

    override public long Spin(int speed)
    {
        // Spin code goes here.
    }
}
```

When implementing an abstract class, you must implement each abstract (**MustOverride**) method in that class, and each implemented method must receive the same number and type of arguments, and have the same return value, as the method specified in the abstract class.

Interface Definition and Factoring Design Considerations

Interfaces can be useful tools when used properly. But when used improperly, they can be cumbersome, or even become hindrances to efficient programming. The following section will provide recommendations for the best design and use of interfaces.

> **Caution** An interface once defined and accepted must remain invariant, to protect applications written to use it. Do not change interfaces once you have published them.

Interface Invariance

When you create an interface, you are creating a definition that can never change after the interface definition has been released. This *interface invariance* is an important principle of component design, because it protects existing systems that have been written to use the interface.

When an interface is clearly in need of enhancement, a new interface should be created. This interface might be named by appending a "2" onto the original interface name, to show its relationship to the existing interface.

Generating new interfaces too frequently can bulk up your components with unused interface implementations. Well-designed interfaces tend to be small and independent of each other, reducing the potential for performance problems.

Factoring Interfaces

The process of determining what properties and methods belong on an interface is called *factoring*.

In general, you should group a few closely related functions in an interface. Too many functions make the interface unwieldy, while dividing the parts of a feature too finely results in extra overhead and diminished ease of use. For example, the following code calls methods on two different interfaces of the BusinessAccount class:

```
' Visual Basic
Public Sub MergeAccounts (ByVal act1 As _
      BusinessAccount, ByVal act2 As BusinessAccount)
   Dim pac As IAccount = act1
   Dim company As ICustomer = act1
   act1.Merge(act2)
   company.ChangeAddress()
   pac.PostInterest
End Sub

// C#
public void MergeAccounts(BusinessAccount account1,
   BusinessAccount account2)
{
   IAccount account = account1;
   ICustomer customer = account1;
   account1.Merge(account2);
   customer.ChangeAddress();
   account.PostInterest();
}
```

It is much harder to go wrong in designing interfaces than in creating large inheritance trees. If you start small, you can have parts of a system running relatively quickly. The ability to evolve the system by adding interfaces allows you to gain the advantages object-oriented programming was intended to provide.

> **Note** The capital "I" in front of interface names is a convention. It is not strictly necessary to follow this convention. However, it provides an easy way to distinguish between interfaces and the classes that implement them.

See Also

Polymorphism in Components

Implementing Existing Interfaces

An interface is a contract. It defines a standard set of properties, methods, and events that are to be found in any class that implements the interface. This insures that if your class for example implements IWidget, any other class that expects to interact with IWidget can interact with your class, regardless of what other functions your class may perform.

Interfaces and their member functions and properties are implemented in Visual Basic using the **Implements** keyword. In C#, interfaces to be implemented follow a colon (:) in the class declaration and are separated on a single line by commas.

The property and method definitions must take the exact form defined by the interface. For example, say you were implementing the following interface:

```
' Visual Basic
Public Interface IAccount
   Sub DeductFees(Fees as IFeeSchedule)
   Sub PostInterest()
   Property Balance() As Decimal
End Interface

// C#
public interface IAccount
{
   void DeductFees(IFeeSchedule feeSchedule);
   void PostInterest();
   decimal Balance
   {
      get;
      set;
   }
}
```

In the code that you would write to implement these properties and methods, you would have to follow the construction of these procedures exactly. For instance, the following line would be illegal:

```
' Visual Basic
Public Property MyBalance() As Double Implements IAccount.Balance

// C#
double IAccount.MyBalance
```

This line is not a legal implementation of the interface because it declares the property as a double, instead of an integer. Likewise, a method must take the same number and type of arguments as are defined in the interface. It also has to have the same name.

To implement an existing interface

1. Declare a class using the standard syntax.
2. Within the class declaration, define the interface you are implementing. A single class may implement more than one interface.

   The following examples show how to specify that the IAccount, ICustomer, and IPortfolio interfaces be implemented:

   ```
   ' Visual Basic
   Public Class BusinessAccount
      Implements IAccount
      Implements ICustomer
      Implements IPortfolio
      ' Code to implement class here.
   End Class

   // C#
   public class BusinessAccount : IAccount, ICustomer, IPortfolio
   {
   ```

```
    // Code to implement class here.
}
```

3. Implement each property and method required by the interface. Examples are shown below:

```
' Visual Basic
Public Sub BuyEquity() Implements IPortfolio.PurchaseEquity
   ' Code to carry out ths procedure goes here.
End Sub

Public Property Balance() as Decimal Implements IAccount.Balance
   ' Appropriate code goes here.
End Property

Public Function ChangeAddress(NewAddress as IAddress) as Boolean _
   Implements ICustomer.ChangeAddress
   ' Appropriate code is here.
End Function

// C#
bool ICustomer.ChangeAddress(IAddress newAddress)
{
   // Appropriate code goes here.
}

void IPortfolio.BuyEquity()
{
   // Code to carry out this procedure goes here.
}

public decimal Balance
{
   // Appropriate code goes here.
}
```

Note In Visual C#, you cannot implement an interface member with a method of a different name, such as you can in Visual Basic .NET using the **Implements** keyword.

4. Write any other code you require your class to contain.

Interface Definition and Factoring Design Considerations | Design Recommendations for Interfaces and Components | Recommendations for Abstract Classes vs. Interfaces

Recommendations for Abstract Classes vs. Interfaces

The choice of whether to design your functionality as an interface or an abstract class (a **MustInherit** class in Visual Basic) can sometimes be a difficult one. An *abstract class* is a class that cannot be instantiated, but must be inherited from. An abstract class may be fully implemented, but is more usually partially implemented or not implemented at all, thereby encapsulating common functionality for inherited classes. For details, see Abstract Classes.

An *interface*, by contrast, is a totally abstract set of members that can be thought of as defining a contract for conduct. The implementation of an interface is left completely to the developer.

Both interfaces and abstract classes are useful for component interaction. If a method requires an interface as an argument, then any object that implements that interface can be used in the argument. For example:

```
' Visual Basic
Public Sub Spin (ByVal widget As IWidget)
End Sub
// C#
public void Spin (IWidget widget)
{}
```

This method could accept any object that implemented IWidget as the widget argument, even though the implementations of IWidget might be quite different. Abstract classes also allow for this kind of polymorphism, but with a few caveats:

- Classes may inherit from only one base class, so if you want to use abstract classes to provide polymorphism to a group of classes, they must all inherit from that class.
- Abstract classes may also provide members that have already been implemented. Therefore, you can ensure a certain amount of identical functionality with an abstract class, but cannot with an interface.

Here are some recommendations to help you to decide whether to use an interface or an abstract class to provide polymorphism for your components.

- If you anticipate creating multiple versions of your component, create an abstract class. Abstract classes provide a simple and easy way to version your components. By updating the base class, all inheriting classes are automatically updated with the change. Interfaces, on the other hand, cannot be changed once created. If a new version of an interface is required, you must create a whole new interface.
- If the functionality you are creating will be useful across a wide range of disparate objects, use an interface. Abstract classes should be used primarily for objects that are closely related, whereas interfaces are best suited for providing common functionality to unrelated classes.
- If you are designing small, concise bits of functionality, use interfaces. If you are designing large functional units, use an abstract class.
- If you want to provide common, implemented functionality among all implementations of your component, use an abstract class. Abstract classes allow you to partially implement your class, whereas interfaces contain no implementation for any members.

See Also

Abstract Classes | Polymorphism in Components | MustInherit (Visual Basic) | abstract (C#)

Design Recommendations for Interfaces and Components

A key advantage of component software development using multiple interfaces is that your components can evolve by implementing additional interfaces as the need for new functionality arises. For example: As the BankManager system evolves into, say, the BrokerageManagement system, components that provide savings and checking account objects can be replaced by components that provide MoneyMarketAccount and MultiUseAccount objects.

A legacy application compiled to use personal accounts may be still be able to function quite nicely using the new account classes, as long as it doesn't include code specific to personal accounts.

- The key points to remember when using multiple interfaces in this fashion are: After an interface is defined and in use, it must never change. For details about *interface invariance, see* Interface Definition and Factoring Design Considerations.
- If an interface needs to be expanded, create a new interface. For details, see Interface Definition and Factoring Design Considerations.
- If versioning is an anticipated issue, consider creating an *abstract class*. Abstract classes are classes that must be implemented and cannot be instantiated on their own. An abstract class can be versioned by adding additional methods, properties and events as the need arises. By making the required change to the base class, the inheriting classes can incorporate new functionality without the need for changing all of the references to that class, as you would have to do with an interface. For details, see Recommendations for Abstract Classes vs. Interfaces.
- New versions of components can provide new features by implementing new and expanded interfaces.
- New versions of components can support legacy code by continuing to provide old interfaces.
- New versions of applications can take advantage of new features (that is, new and expanded interfaces), and if necessary can be written so as to degrade gracefully when only older interfaces are available.

Polymorphism in Components | Abstract Classes

Interface Implementation Examples

After you have identified an existing interface that would be useful to your component, or defined interfaces of your own, you can implement that interface in classes your components provide.

Suppose you had a BankManager system that included a number of components, each of which provided objects representing accounts, transactions, and business rules. For example, one component might provide a BusinessAccount class, while another provided a PersonalAccount class.

Defining a Standard Interface

You might create a standard interface named IAccount, which included PostInterest and DeductFees methods:

```
' Visual Basic code for the abstract IAccount interface module.
Public Interface IAccount
   Sub PostInterest()
   Sub DeductFees(ByVal FeeSchedule As IFeeSchedule)
End Interface

// C#
// Code for the IAccount interface module.
public interface IAccount
{
   void PostInterest();
   void DeductFees(IFeeSchedule feeSchedule);
}
```

Notice that the argument of the DeductFees method uses another interface, IFeeSchedule. One would expect this interface to contain methods describing general customer attributes, such as calculating fees for various account transactions, and that it would be implemented by many classes — BusinessAccount, PersonalAccount, PreferredAccount, and so on.

Notice also that there is no code in these methods. IAccount simply defines the interface. Implementation details will vary according to the object that implements the interface.

Implementing the Standard Interface

For example, the BusinessAccount class might implement IAccount as follows:

```
' Visual Basic
Public Class BusinessAccount
Implements IAccount

Private Sub PostInterest() Implements Iaccount.PostInterest
   ' Code to post interest using the most favorable rate.
End Sub

Private Sub DeductFees(ByVal FeeSchedule As IFeeSchedule) Implements _
   Iaccount.PostInterest
   ' Code to charge a preferred rate for various services.
End Sub
End Class

// C#
class BusinessAccount : IAccount
{
   void IAccount.PostInterest()
   {
      // Code to post interest using the most favorable rate.
   }

   void IAccount.DeductFees(IFeeSchedule feeSchedule)
   {
      // Code to change a preferred rate for various services.
   }
}
```

Note An interface is a contract. You must implement all of the properties and methods in the interface. For details, see Implementing Existing Interfaces.

Implementing the Interface Differently in Another Class

By contrast, the PersonalAccount class might implement IAccount, as shown in the following examples:

```
' Visual Basic
Public Class PersonalAccount
Implements IAccount

Private Sub PostInterest() Implements IAccount.PostInterest
   ' Calculate interest for a small account and post it.
End Sub

Private Sub DeductFees(ByVal FeeSchedule As IFeeSchedule) Implements _
   IAccount.DeductFees
   ' Calculate how many service interactions the customer has
   ' had and charge accordingly.
End Sub
End Class

// C#
class PersonalAccount : IAccount
{
   void IAccount.PostInterest()
   {
      // Calculate interest for a small account and post it.
   }

   void IAccount.DeductFees(IFeeSchedule feeSchedule)
   {
      // Calculate how many service interactions the customer
      // has had and charge accordingly.
   }
}
```

Upgrading Applications to Use a New Interface

Once you have classes that implement IAccount, you can upgrade your existing applications one by one to use the new, more competitive interface. You can access the PostInterest and DeductFees methods by assigning a BusinessAccount or PersonalAccount object to a variable of type IAccount, as shown in the following examples:

```
' Visual Basic
Dim bus As New BusinessAccount
Dim act As IAccount
act = bus
act.PostInterest()

// C#
BusinessAccount business = new BusinessAccount();
IAccount account = business;
account.PostInterest();
```

You can also declare procedure arguments as IAccount, and pass the procedure any object that implements the IAccount interface, as shown in the following examples:

```
' Visual Basic
Public Sub AccountMaintenence(ByVal Account As _
      IAccount, ByVal FeeSchedule As IFeeSchedule)
   Account.PostInterest
   Account.DeductFees(FeeSchedule)
End Sub
```

```
// C#
public void AccountMaintenance(IAccount account, IFeeSchedule feeSchedule)
{
   account.PostInterest();
   account.DeductFees(feeSchedule);
}
```

The procedure shown above could be called with any account as the first argument, and any fee schedule as the second. The caller of the procedure can use whatever account is most appropriate for the occasion.

Multithreading in Components

Multithreading, or *free threading*, refers to the ability of a program to execute multiple threads of operation simultaneously. An example of a multithreaded application might be a program that receives user input on one thread, performs a variety of complex calculations on a second thread, and updates a database on a third thread. In a single-threaded application, a user might spend idle time waiting for the calculations or database updates to finish. In a multithreaded application, these processes can proceed in the background so user time is not wasted.

Multithreading can be a powerful tool to use in component programming. By writing multithreaded components, you can create components that perform complex calculations in the background while leaving the user interface free to respond to user input.

Although multithreading can be a powerful tool, it can also be difficult to apply correctly. Improperly implemented multithreaded code can degrade application performance, or even cause frozen applications. The following topics will introduce you to some of the considerations and best practices for multithreaded programming.

Walkthrough: Authoring a Simple Multithreaded Component with Visual Basic

You can write applications that are able to perform multiple tasks simultaneously. This ability, called *multithreading*, or *free threading*, is a powerful way to design components that are processor-intensive and require user input. An example of a component that might make use of multithreading would be a component that calculates payroll information. The component could process data entered into a database by a user on one thread while processor-intensive payroll calculations were performed on another. By running these processes on separate threads, users do not need to wait for the computer to complete calculations before entering additional data. In this walkthrough, you will create a simple multithreaded component that performs multiple complex calculations simultaneously.

Creating the Project

Your application will consist of a single form and a component. The user will input values and signal to the component to begin calculations. The form will then receive values from your component and display them in label controls. The component will perform the processor-intensive calculations and signal the form when complete. You will create public variables in your component to hold values received from your user interface. You will also implement methods in your component to perform the calculations based on the values of these variables.

> **Note** While a function is usually preferable for a method that calculates a value, arguments cannot be passed between threads, nor can values be returned. There are many simple ways to supply values to threads and to receive values from them. In this demonstration, you will return values to your user interface by updating public variables, and events will be used to notify the main program when a thread has completed execution.

To create the form

1. Create a new **Windows Application** project.
2. Name the application **Calculations** and rename **Form1.vb** as **frmCalculations.vb**.

   This form will serve as the primary user interface for your application.

3. Add five **Label** controls, four **Button** controls, and one **TextBox** control to your form. Set properties for these controls as follows.

Control	Name	Text
Label1	**lblFactorial1**	(blank)
Label2	**lblFactorial2**	(blank)
Label3	**lblAddTwo**	(blank)
Label4	**lblRunLoops**	(blank)
Label5	**lblTotalCalculations**	(blank)
Button1	**btnFactorial1**	**Factorial**
Button2	**btnFactorial2**	**Factorial - 1**
Button3	**btnAddTwo**	**Add Two**
Button4	**btnRunLoops**	**Run a Loop**
TextBox1	**txtValue**	(blank)

To create the Calculator component

1. From the **Project** menu, select **Add Component**.
2. Name this component **Calculator**.

To add public variables to the Calculator component

1. Open the Code Editor for **Calculator**.
2. Add statements to create public variables that you will use to pass values from **frmCalculations** to each thread.

   The variable `varTotalCalculations` will keep a running total of the total number of calculations performed by the component, and the other variables will receive values from the form.

```
Public varAddTwo As Integer
Public varFact1 As Integer
```

```
Public varFact2 As Integer
Public varLoopValue As Integer
Public varTotalCalculations As Double = 0
```

To add methods and events to the Calculator component

1. Declare the events that your component will use to communicate values to your form. Immediately beneath the variable declarations entered in the previous step, type the following code:

```
Public Event FactorialComplete(ByVal Factorial As Double, ByVal _
   TotalCalculations As Double)
Public Event FactorialMinusComplete(ByVal Factorial As Double, ByVal _
   TotalCalculations As Double)
Public Event AddTwoComplete(ByVal Result As Integer, ByVal _
   TotalCalculations As Double)
Public Event LoopComplete(ByVal TotalCalculations As Double, ByVal _
   Counter As Integer)
```

2. Immediately beneath the variable declarations entered in step 1, type the following code:

```
' This sub will calculate the value of a number minus 1 factorial
' (varFact2-1!).
Public Sub FactorialMinusOne()
   Dim varX As Integer = 1
   Dim varTotalAsOfNow As Double
   Dim varResult As Double = 1
   ' Performs a factorial calculation on varFact2 - 1.
   For varX = 1 to varFact2 - 1
      varResult *= varX
      ' Increments varTotalCalculations and keeps track of the current
      ' total as of this instant.
      varTotalCalculations += 1
      varTotalAsOfNow = varTotalCalculations
   Next varX
   ' Signals that the method has completed, and communicates the
   ' result and a value of total calculations performed up to this
   ' point
   RaiseEvent FactorialMinusComplete(varResult, varTotalAsOfNow)
End Sub

' This sub will calculate the value of a number factorial (varFact1!).
Public Sub Factorial()
   Dim varX As Integer = 1
   Dim varResult As Double = 1
   Dim varTotalAsOfNow As Double = 0
   For varX = 1 to varFact1
       varResult *= varX
       varTotalCalculations += 1
       varTotalAsOfNow = varTotalCalculations
   Next varX
   RaiseEvent FactorialComplete(varResult, varTotalAsOfNow)
End Sub

' This sub will add two to a number (varAddTwo + 2).
Public Sub AddTwo()
   Dim varResult As Integer
   Dim varTotalAsOfNow As Double
   varResult = varAddTwo + 2
   varTotalCalculations += 1
```

```
    varTotalAsOfNow = varTotalCalculations
    RaiseEvent AddTwoComplete(varResult, varTotalAsOfNow)
End Sub

' This method will run a loop with a nested loop varLoopValue times.
Public Sub RunALoop()
    Dim varX As Integer
    Dim varY As Integer
    Dim varTotalAsOfNow As Double
    For varX = 1 To varLoopValue
        ' This nested loop is added solely for the purpose of slowing
        ' down the program and creating a processor-intensive
        ' application.
        For varY = 1 To 500
            varTotalCalculations += 1
            varTotalAsOfNow = varTotalCalculations
        Next
    Next
    RaiseEvent LoopComplete(varTotalAsOfNow, varX - 1)
End Sub
```

Transferring User Input to the Component

The next step is to add code to **frmCalculations** to receive input from the user and to transfer and receive values to and from the Calculator component.

To implement front-end functionality to frmCalculations

1. Open **frmCalculations** in the Code Editor.
2. Locate the `Inherits System.Windows.Forms.Form` statement. Immediately beneath it type:

```
Dim WithEvents Calculator1 As Calculator
```

3. Locate `Public Sub New()`. Immediately before the `End Sub` statement, add the following line:

```
' Creates a new instance of Calculator.
Calculator1 = New Calculator
```

4. Locate the `End Class` statement at the bottom of the Code Editor. Immediately above it, add the following code to handle button clicks:

```
Protected Sub btnFactorial1_Click(ByVal sender As Object, ByVal e As _
    System.EventArgs) Handles btnFactorial1.Click
    ' Passes the value typed in the txtValue to Calculator.varFact1.
    Calculator1.varFact1 = CInt(txtValue.Text)
    ' Disables the btnFactorial1 until this calculation is complete.
    btnFactorial1.Enabled = False
    Calculator1.Factorial()
End Sub

Protected Sub btnFactorial2_Click(ByVal sender As Object, ByVal e _
    As System.EventArgs) Handles btnFactorial2.Click
    Calculator1.varFact2 = CInt(txtValue.Text)
    btnFactorial2.Enabled = False
    Calculator1.FactorialMinusOne()
End Sub

Protected Sub btnAddTwo_Click(ByVal sender As Object, ByVal e As _
    System.EventArgs) Handles btnAddTwo.Click
    Calculator1.varAddTwo = CInt(txtValue.Text)
```

```
    btnAddTwo.Enabled = False
    Calculator1.AddTwo()
End Sub

Protected Sub btnRunLoops_Click(ByVal sender As Object, ByVal e As _
    System.EventArgs) Handles btnRunLoops.Click
    Calculator1.varLoopValue = CInt(txtValue.Text)
    btnRunLoops.Enabled = False
    ' Lets the user know that a loop is running.
    lblRunLoops.Text = "Looping"
    Calculator1.RunALoop()
End Sub
```

5. Beneath the code you added in the previous step, type the following to handle the events your form will receive from **Calculator1**:

```
Protected Sub FactorialHandler(ByVal Value As Double, ByVal _
    Calculations As Double)
    ' Displays the returned value in the appropriate label.
    lblFactorial1.Text = Value.ToString
    ' Re-enables the button so it can be used again.
    btnFactorial1.Enabled = True
    ' Updates the label that displays the total calculations performed
    lblTotalCalculations.Text = "TotalCalculations are " & _
       Calculations.ToString
End Sub

Protected Sub Factorial1Handler(ByVal Value As Double, ByVal _
    Calculations As Double)
    lblFactorial2.Text = Value.ToString
    btnFactorial2.Enabled = True
    lblTotalCalculations.Text = "TotalCalculations are " & _
        Calculations.ToString
End Sub

Protected Sub AddTwoHandler(ByVal Value As Integer, ByVal _
    Calculations As Double)
    lblAddTwo.Text = Value.ToString
    btnAddTwo.Enabled = True
    lblTotalCalculations.Text = "TotalCalculations are " & _
        Calculations.ToString
End Sub

Protected Sub LoopDoneHandler(ByVal Calculations As Double, ByVal _
    Count As Integer)
    btnRunLoops.Enabled = True
    lblRunLoops.Text = Count.ToString
    lblTotalCalculations.Text = "TotalCalculations are " & _
       Calculations.ToString
End Sub
```

6. In the constructor of **frmCalculations**, add the following code immediately before the **End Sub** line to handle the custom events your form will receive from **Calculator1**:

```
AddHandler Calculator1.FactorialComplete, AddressOf FactorialHandler
AddHandler Calculator1.AddTwoComplete, AddressOf AddTwoHandler
AddHandler Calculator1.FactorialMinusComplete, AddressOf _
    Factorial1Handler
AddHandler Calculator1.LoopComplete, AddressOf LoopDoneHandler
```

These statements add event handlers to handle the custom events your form will receive from **Calculator1**. The AddressOf Operator creates a delegate to the procedure that is specified, and the AddHandler Statement designates that delegate to handle the event specified.

Testing Your Application

You have now created a project that incorporates a form and a component capable of performing several complex calculations. Though you have not implemented multithreading capability yet, you will test your project to verify its functionality before proceeding.

To test your project

1. From the **Debug** menu, choose **Start**. The application begins and **frmCalculations** appears.
2. In the text box, type **4**, then click the button labeled **Add two**.

   The numeral "6" should be displayed in the label beneath it, and "Total Calculations are 1" should be displayed in **lblTotalCalculations**.

3. Now click the button labeled **Factorial - 1**.

   The numeral "6" should be displayed beneath the button, and **lblTotalCalculations** now reads "Total Calculations are 4."

4. Change the value in the text box to **20**, then click the button labeled **Factorial**.

   The number "2.43290200817664E+18" is displayed beneath it, and **lblTotalCalculations** now reads "Total Calculations are 24."

5. Change the value in the text box to **50000**, and then click the button labeled **RunALoop**.

   Note that there is a small but noticeable interval before this button is reenabled. The label under this button should read "50000" and the total calculations displayed are "25000024."

6. Change the value in the text box to **5000000** and click the button labeled **Run A Loop**, then immediately click the button labeled **Add Two**. Click it again.

   The button does not respond, nor will any control on the form respond until the loops have been completed.

   If your program runs only a single thread of execution, processor-intensive calculations such as the above example have the tendency to tie up the program until the calculations have been completed. In the next section, you will add multithreading capability to your application so that multiple threads may be run at once.

Adding Multithreading Capability

The previous example demonstrated the limitations of applications that run only a single thread of execution. In the next section you will use the Thread Class to add multiple threads of execution to your component.

To add the Threads subroutine

1. Open **Calculator.vb** in the Code Editor. Near the top of the code, locate the `Inherits System.ComponentModel.Component` line. Immediately beneath it, type the following:

```
' Declares the variables you will use to hold your thread objects.
Public FactorialThread As System.Threading.Thread
Public FactorialMinusOneThread As System.Threading.Thread
Public AddTwoThread As System.Threading.Thread
Public LoopThread As System.Threading.Thread
```

2. Immediately before the `End Class` statement at the bottom of the code, add the following method:

```
Public Sub ChooseThreads(ByVal threadNumber As Integer)
' Determines which thread to start based on the value it receives.
   Select Case threadNumber
      Case 1
         ' Sets the thread using the AddressOf the subroutine where
         ' the thread will start.
         FactorialThread = New System.Threading.Thread(AddressOf _
```

```
            Factorial)
         ' Starts the thread.
         FactorialThread.Start()
      Case 2
         FactorialMinusOneThread = New _
            System.Threading.Thread(AddressOf FactorialMinusOne)
         FactorialMinusOneThread.Start()
      Case 3
         AddTwoThread = New System.Threading.Thread(AddressOf AddTwo)
         AddTwoThread.Start()
      Case 4
         LoopThread = New System.Threading.Thread(AddressOf RunALoop)
         LoopThread.Start()
   End Select
End Sub
```

When a **Thread** object is instantiated, it requires an argument in the form of a **ThreadStart** object. The **ThreadStart** object is a delegate that points to the address of the subroutine where the thread is to begin. A **ThreadStart** object cannot take parameters or pass values, and thus cannot indicate a function. The **AddressOf** operator returns a delegate that serves as the **ThreadStart** object. The **ChooseThreads** sub you just implemented will receive a value from the program calling it and use that value to determine the appropriate thread to start.

To add the thread-starting code to frmCalculations

1. Open the **frmCalculations.vb** file in the Code Editor. Locate `Sub btnFactorial1_Click`.
   a. Comment out the line that calls the **Calculator1.Factorial** method directly as shown:

   ```
   ' Calculator1.Factorial
   ```

   b. Add the following line to call the **Calculator1.ChooseThreads** method:

   ```
   ' Passes the value 1 to Calculator1, thus directing it to start the ' correct thread
   .
   Calculator1.ChooseThreads(1)
   ```

2. Make similar modifications to the other button_click subroutines.

   Note Be sure to include the appropriate value for the threads argument.

   When you have finished, your code should look similar to the following:

```
Protected Sub btnFactorial1_Click(ByVal sender As Object, ByVal e As _
   System.EventArgs) Handles btnFactorial1.Click
   ' Passes the value typed in the txtValue to Calculator.varFact1.
   Calculator1.varFact1 = CInt(txtValue.Text)
   ' Disables the btnFactorial1 until this calculation is complete.
   btnFactorial1.Enabled = False
   ' Calculator1.Factorial()
   ' Passes the value 1 to Calculator1, thus directing it to start the
   ' Correct thread.
   Calculator1.ChooseThreads(1)
End Sub

Protected Sub btnFactorial2_Click(ByVal sender As Object, ByVal e As _
   System.EventArgs) Handles btnFactorial2.Click
   Calculator1.varFact2 = CInt(txtValue.Text)
   btnFactorial2.Enabled = False
   ' Calculator1.FactorialMinusOne()
   Calculator1.ChooseThreads(2)
```

```
End Sub

Protected Sub btnAddTwo_Click(ByVal sender As Object, ByVal e As _
   System.EventArgs) Handles btnAddTwo.Click
   Calculator1.varAddTwo = CInt(txtValue.Text)
   btnAddTwo.Enabled = False
   ' Calculator1.AddTwo()
   Calculator1.ChooseThreads(3)
End Sub

Protected Sub btnRunLoops_Click(ByVal sender As Object, ByVal e As _
   System.EventArgs) Handles btnRunLoops.Click
   Calculator1.varLoopValue = CInt(txtValue.Text)
   btnRunLoops.Enabled = False
   ' Lets the user know that a loop is running.
   lblRunLoops.Text = "Looping"
   ' Calculator1.RunALoop()
   Calculator1.ChooseThreads(4)
End Sub
```

Marshalling Calls to Controls

You will now facilitate updating the display on the form. Because controls are always owned by the main thread of execution, any call to a control from a subordinate thread requires a *marshalling* call. Marshalling is the act of moving a call across thread boundaries, and is very expensive in terms of resources. To minimize the amount of marshalling that needs to occur, and to be sure that your calls are handled in a thread-safe manner, you will use the Control.BeginInvoke Method to invoke methods on the main thread of execution, thereby minimizing the amount of cross-thread-boundary marshalling that must occur. This kind of call is necessary when calling methods that manipulate controls. For further information, see Manipulating Controls From Threads.

To create the control-invoking procedures

1. Open the Code Editor for **frmCalculations**. In the declarations section, add the following code.

```
Public Delegate Sub FHandler(ByVal Value As Double, ByVal _
   Calculations As Double)
Public Delegate Sub A2Handler(ByVal Value As Integer, ByVal _
   Calculations As Double)
Public Delegate Sub LDhandler(ByVal Calculations As Double, ByVal _
   Count As Integer)
```

   Invoke and **BeginInvoke** require a delegate to the appropriate method as an argument. These lines declare the delegate signatures that will be used by **BeginInvoke** to invoke the appropriate methods.

2. Add the following empty methods to your code.

```
Public Sub FactHandler(ByVal Value As Double, ByVal Calculations As _
   Double)
End Sub
Public Sub Fact1Handler(ByVal Value As Double, ByVal Calculations As _
   Double)
End Sub
Public Sub Add2Handler(ByVal Value As Integer, ByVal Calculations As _
   Double)
End Sub
Public Sub LDoneHandler(ByVal Calculations As Double, ByVal Count As _
   Integer)
End Sub
```

3. From the **Edit** menu, use **Cut** and **Paste** to cut all the code from `Sub FactorialHandler` and paste it into `FactHandler`.
4. Repeat the previous step for Factorial1Handler and Fact1Handler, AddTwoHandler and Add2Handler, and

LoopDoneHandler and LDoneHandler.

When finished, there should be no code remaining in `FactorialHandler`, `Factorial1Handler`, `AddTwoHandler`, and `LoopDoneHandler`, and all the code these used to contain should have been moved to the appropriate new methods.

5. Call the **BeginInvoke** method to invoke the methods asynchronously. You can call **BeginInvoke** from either your form (**me**) or any of the controls on the form:

```
Protected Sub FactorialHandler(ByVal Value As Double, ByVal _
   Calculations As Double)
   ' BeginInvoke causes asynchronous execution to begin at the address
   ' specified by the delegate. Simply put, it transfers execution of
   ' this method back to the main thread. Any parameters required by
   ' the method contained at the delegate are wrapped in an object and
   ' passed.
   Me.BeginInvoke(New FHandler(AddressOf FactHandler), New Object() _
      {Value, Calculations})
End Sub

Protected Sub Factorial1Handler(ByVal Value As Double, ByVal _
   Calculations As Double)
   Me.BeginInvoke(New FHandler(AddressOf Fact1Handler), New Object() _
      {Value, Calculations})
End Sub

Protected Sub AddTwoHandler(ByVal Value As Integer, ByVal _
   Calculations As Double)
   Me.BeginInvoke(New A2Handler(AddressOf Add2Handler), New Object() _
      {Value, Calculations})
End Sub

Protected Sub LoopDoneHandler(ByVal Calculations As Double, ByVal _
   Count As Integer)
   Me.BeginInvoke(New LDHandler(AddressOf Ldonehandler), New Object() _
      {Calculations, Count})
End Sub
```

It may seem as though the event handler is simply making a call to the next method. The event handler is actually causing a method to be invoked on the main thread of operation. This approach saves on calls across thread boundaries and allows your multithreaded applications to run efficiently and without fear of causing lockup. For details on working with controls in a multithreaded environment, see Manipulating Controls From Threads

6. Save your work.
7. Test your solution by choosing **Start** from the **Debug** menu.
   a. Type **10000000** in the text box and click **Run A Loop**.

      "Looping" is displayed in the label beneath this button. This loop should take a significant amount of time to run. If it completes too early, adjust the size of the number accordingly.

   b. In rapid succession, click all three buttons that are still enabled. You will find that all buttons respond to your input. The label beneath **Add Two** should be the first to display a result. Results will later be displayed in the labels beneath the factorial buttons. These results evaluate to infinity, as the number returned by a 10,000,000 factorial is too large for a double-precision variable to contain. Finally, after an additional delay, results are returned beneath the **Run A Loop** button.

      As you just observed, four separate sets of calculations were performed simultaneously upon four separate threads. The user interface remained responsive to input, and results were returned after each thread completed.

Coordinating Your Threads

An experienced user of multithreaded applications may perceive a subtle flaw with the code as typed. Recall the lines of code from each calculation-performing subroutine in **Calculator.vb**:

```
varTotalCalculations += 1
varTotalAsOfNow = varTotalCalculations
```

These two lines of code increment the public variable **varTotalCalculations** and set the local variable **varTotalAsOfNow** to this value. This value is then returned to **frmCalculations** and displayed in a label control. But is the correct value being returned? If only a single thread of execution is running, the answer is clearly yes. But if multiple threads are running, the answer becomes more uncertain. Each thread has the ability to increment the variable **varTotalCalculations**. It is possible that after one thread increments this variable, but before it copies the value to **varTotalAsOfNow**, another thread could alter the value of this variable by incrementing it. This leads to the possibility that each thread is, in fact, reporting inaccurate results. Visual Basic provides the SyncLock Statement to allow synchronization of threads to ensure that each thread always returns an accurate result. The syntax for **SyncLock** is as follows:

```
SyncLock AnObject
   Insert code that affects the object
   Insert some more
   Insert even more
' Release the lock
End SyncLock
```

When the **SyncLock** block is entered, execution on the specified expression is blocked until the specified thread has an exclusive lock on the object in question. In the example shown above, execution is blocked on `AnObject`. **SyncLock** must be used with an object that returns a reference rather than a value. The execution may then proceed as a block without interference from other threads. A set of statements that execute as a unit are said to be *atomic*. When **End SyncLock** is encountered, the expression is freed and the threads are allowed to proceed normally.

To add the SyncLock statement to your application

1. Open **Calculator.vb** in the Code Editor.
2. Locate each instance of the following code:

   ```
   varTotalCalculations += 1
   varTotalAsOfNow = varTotalCalculations
   ```

   There should be four instances of this code, one in each calculation method.

3. Modify this code so that it reads as follows:

   ```
   SyncLock Me
      varTotalCalculations += 1
      varTotalAsOfNow = varTotalCalculations
   End SyncLock
   ```

4. Save your work and test it as in the previous example.

   You may notice a slight impact on the performance of your program. This is because execution of threads stops when an exclusive lock is obtained on your component. Although it ensures accuracy, this approach impedes some of the performance benefit of multiple threads. You should carefully consider the need for locking threads, and implement them only when absolutely necessary.

Walkthrough: Authoring a Simple Multithreaded Component with Visual C#

You can write applications that are able to perform multiple tasks simultaneously. This ability, called *multithreading*, or *free threading*, is a powerful way to design components that are processor-intensive and require user input. An example of a component that might make use of multithreading would be a component that calculates payroll information. The component could process data entered into a database by a user on one thread while processor-intensive payroll calculations were performed on another. By running these processes on separate threads, users do not need to wait for the computer to complete calculations before entering additional data. In this walkthrough, you will create a simple multithreaded component that performs several complex calculations simultaneously.

Creating the Project

Your application will consist of a single form and a component. The user will input values and signal to the component to begin calculations. The form will then receive values from your component and display them in label controls. The component will perform the processor-intensive calculations and signal the form when complete. You will create public variables in your component to hold values received from your user interface. You will also implement methods in your component to perform the calculations based on the values of these variables.

> **Note** Although a function is usually preferable for a method that calculates a value, arguments cannot be passed between threads, nor can values be returned. There are many simple ways to supply values to threads and to receive values from them. In this demonstration, you will return values to your user interface by updating public variables, and events will be used to notify the main program when a thread has completed execution.

To create the form

1. Create a new **Windows Application** project.
2. Name the application **Calculations** and rename **Form1.cs** as **frmCalculations.cs**.

   This form will serve as the primary user interface for your application.

3. Double-click the form in the designer to open the **Code Editor**. From the **Edit** menu, choose **Find and Replace**, then **Replace**. Use **Replace All** to replace **Form1** with **frmCalculations**.
4. In the **Solution Explorer**, right-click **frmCalculations.cs** and select **View Designer**. The designer opens.
5. Add five **Label** controls, four **Button** controls, and one **TextBox** control to your form.
6. Set properties for these controls as follows:

Control	Name	Text
Label1	**lblFactorial1**	(blank)
Label2	**lblFactorial2**	(blank)
Label3	**lblAddTwo**	(blank)
Label4	**lblRunLoops**	(blank)
Label5	**lblTotalCalculations**	(blank)
Button1	**btnFactorial1**	**Factorial**
Button2	**btnFactorial2**	**Factorial - 1**
Button3	**btnAddTwo**	**Add Two**
Button4	**btnRunLoops**	**Run a Loop**
Textbox1	**txtValue**	(blank)

To create the Calculator component

1. From the **Project** menu, select **Add Component**.
2. Name the component **Calculator**.

To add public variables to the Calculator component

1. Open the Code Editor for **Calculator**.
2. Add statements to create public variables that you will use to pass values from **frmCalculations** to each thread.

   The variable `varTotalCalculations` will keep a running total of the total number of calculations performed by the component, and the other variables will receive values from the form.

```
public int varAddTwo;
public int varFact1;
public int varFact2;
public int varLoopValue;
public double varTotalCalculations = 0;
```

To add methods and events to the Calculator component

1. Declare the delegates for the events that your component will use to communicate values to your form.

   Note Although you will be declaring four events, you only need to create three delegates, because two events will have the same signature.

   Immediately beneath the variable declarations entered in the previous step, type the following code:

```
// This delegate will be invoked with two of your events.
public delegate void FactorialCompleteHandler(double Factorial, double TotalCalculations)
;
public delegate void AddTwoCompleteHandler(int Result, double TotalCalculations);
public delegate void LoopCompleteHandler(double TotalCalculations, int Counter);
```

2. Declare the events that your component will use to communicate with your application. Do this by adding the following code immediately beneath the code entered in the previous step.

```
public event FactorialCompleteHandler FactorialComplete;
public event FactorialCompleteHandler FactorialMinusOneComplete;
public event AddTwoCompleteHandler AddTwoComplete;
public event LoopCompleteHandler LoopComplete;
```

3. Immediately beneath the code you typed in the previous step, type the following code:

```
// This method will calculate the value of a number minus 1 factorial
// (varFact2-1!).
public void FactorialMinusOne()
{
   double varTotalAsOfNow = 0;
   double varResult = 1;
   // Performs a factorial calculation on varFact2 - 1.
   for (int varX = 1; varX <= varFact2 - 1; varX++)
   {
      varResult *= varX;
      // Increments varTotalCalculations and keeps track of the current
      // total as of this instant.
      varTotalCalculations += 1;
      varTotalAsOfNow = varTotalCalculations;
   }
   // Signals that the method has completed, and communicates the
   // result and a value of total calculations performed up to this
   // point.
   FactorialMinusOneComplete(varResult, varTotalAsOfNow);
}

// This method will calculate the value of a number factorial.
// (varFact1!)
public void Factorial()
{
   double varResult = 1;
   double varTotalAsOfNow = 0;
   for (int varX = 1; varX <= varFact1; varX++)
```

```
    {
       varResult *= varX;
       varTotalCalculations += 1;
       varTotalAsOfNow = varTotalCalculations;
    }
    FactorialComplete(varResult, varTotalAsOfNow);
 }

 // This method will add two to a number (varAddTwo+2).
 public void AddTwo()
 {
    double varTotalAsOfNow = 0;
    int varResult = varAddTwo + 2;
    varTotalCalculations += 1;
    varTotalAsOfNow = varTotalCalculations;
    AddTwoComplete(varResult, varTotalAsOfNow);
 }

 // This method will run a loop with a nested loop varLoopValue times.
 public void RunALoop()
 {
    int varX;
    double varTotalAsOfNow = 0;
    for (varX = 1; varX <= varLoopValue; varX++)
    {
     // This nested loop is added solely for the purpose of slowing down
     // the program and creating a processor-intensive application.
       for (int varY = 1; varY <= 500; varY++)
       {
          varTotalCalculations += 1;
          varTotalAsOfNow = varTotalCalculations;
       }
    }
    LoopComplete(varTotalAsOfNow, varLoopValue);
 }
```

Transferring User Input to the Component

The next step is to add code to **frmCalculations** to receive input from the user and to transfer and receive values to and from the Calculator component.

To implement front-end functionality to frmCalculations

1. Open **frmCalculations** in the Code Editor.
2. Locate the `public class frmCalculations` statement. Immediately beneath the `{` type:

   ```
   Calculator Calculator1;
   ```

3. Locate the constructor. Immediately before the `}`, add the following line:

   ```
   // Creates a new instance of Calculator.
   Calculator1 = new Calculator();
   ```

4. In the designer, click each button to generate the code outline for each control's click event handlers and add code to create the handlers.

   When complete, your click event handlers should resemble the following:

   ```
   private void btnFactorial1_Click(object sender, System.EventArgs e)
   // Passes the value typed in the txtValue to Calculator.varFact1.
   ```

```
{
   Calculator1.varFact1 = int.Parse(txtValue.Text);
   // Disables the btnFactorial1 until this calculation is complete.
   btnFactorial1.Enabled = false;
   Calculator1.Factorial();
}

private void btnFactorial2_Click(object sender, System.EventArgs e)
{
   Calculator1.varFact2 = int.Parse(txtValue.Text);
   btnFactorial2.Enabled = false;
   Calculator1.FactorialMinusOne();
}
private void btnAddTwo_Click(object sender, System.EventArgs e)
{
   Calculator1.varAddTwo = int.Parse(txtValue.Text);
   btnAddTwo.Enabled = false;
   Calculator1.AddTwo();
}
private void btnRunLoops_Click(object sender, System.EventArgs e)
{
   Calculator1.varLoopValue = int.Parse(txtValue.Text);
   btnRunLoops.Enabled = false;
   // Lets the user know that a loop is running
   lblRunLoops.Text = "Looping";
   Calculator1.RunALoop();
}
```

5. Beneath the code you added in the previous step, type the following to handle the events your form will receive from **Calculator1**:

```
protected void FactorialHandler(double Value, double Calculations)
// Displays the returned value in the appropriate label.
{
   lblFactorial1.Text = Value.ToString();
   // Re-enables the button so it can be used again.
   btnFactorial1.Enabled = true;
   // Updates the label that displays the total calculations performed
   lblTotalCalculations.Text = "TotalCalculations are " +
      Calculations.ToString();
}

protected void FactorialMinusHandler(double Value, double Calculations)
{
   lblFactorial2.Text = Value.ToString();
   btnFactorial2.Enabled = true;
   lblTotalCalculations.Text = "TotalCalculations are " +
      Calculations.ToString();
}

protected void AddTwoHandler(int Value, double Calculations)
{
   lblAddTwo.Text = Value.ToString();
   btnAddTwo.Enabled = true;
   lblTotalCalculations.Text = "TotalCalculations are " +
      Calculations.ToString();
}

protected void LoopDoneHandler(double Calculations, int Count)
```

```
{
   btnRunLoops.Enabled = true;
   lblRunLoops.Text = Count.ToString();
   lblTotalCalculations.Text = "TotalCalculations are " +
      Calculations.ToString();
}
```

6. In the constructor of **frmCalculations**, add the following code immediately before the **}** to handle the custom events your form will receive from **Calculator1**.

```
Calculator1.FactorialComplete += new
   Calculator.FactorialCompleteHandler(this.FactorialHandler);
Calculator1.FactorialMinusOneComplete += new
   Calculator.FactorialCompleteHandler(this.FactorialMinusHandler);
Calculator1.AddTwoComplete += new
   Calculator.AddTwoCompleteHandler(this.AddTwoHandler);
Calculator1.LoopComplete += new
   Calculator.LoopCompleteHandler(this.LoopDoneHandler);
```

Testing Your Application

You have now created a project that incorporates a form and a component capable of performing several complex calculations. Although you have not implemented multithreading capability yet, you will test your project to verify its functionality before proceeding.

To test your project

1. From the **Debug** menu, choose **Start**.

   The application begins and **frmCalculations** appears.

2. In the text box, type **4**, then click the button labeled **Add two**.

   The numeral "6" should be displayed in the label beneath it, and "Total Calculations are 1" should be displayed in **lblTotalCalculations**.

3. Now click the button labeled **Factorial - 1**.

   The numeral "6" should be displayed beneath the button, and **lblTotalCalculations** now reads "Total Calculations are 4."

4. Change the value in the text box to **20**, then click the button labeled **Factorial**.

   The number "2.43290200817664E+18" is displayed beneath it, and **lblTotalCalculations** now reads "Total Calculations are 24."

5. Change the value in the text box to **50000**, and then click the button labeled **RunALoop**.

   Note that there is a small but noticeable interval before this button is reenabled. The label under this button should read "50000" and the total calculations displayed are "25000024."

6. Change the value in the text box to **5000000** and click the button labeled **Run A Loop**, then immediately click the button labeled **Add Two**. Click it again.

   The button does not respond, nor will any control on the form respond until the loops have been completed.

   If your program runs only a single thread of execution, processor-intensive calculations such as the above example have the tendency to tie up the program until the calculations have been completed. In the next section, you will add multithreading capability to your application so that multiple threads may be run at once.

Adding Multithreading Capability

The previous example demonstrated the limitations of applications that run only a single thread of execution. In the next section you will use the Thread Class object to add multiple threads of execution to your component.

To add the Threads subroutine

1. Open **Calculator.cs** in the Code Editor.

2. Near the top of the code, locate the class declaration, and immediately beneath the `{`, type the following:

```
// Declares the variables you will use to hold your thread objects.
public System.Threading.Thread FactorialThread;
public System.Threading.Thread FactorialMinusOneThread;
public System.Threading.Thread AddTwoThread;
public System.Threading.Thread LoopThread;
```

3. Immediately before the end of the class declaration at the bottom of the code, add the following method:

```
public void ChooseThreads(int threadNumber)
{
// Determines which thread to start based on the value it receives.
switch(threadNumber)
   {
      case 1:
         // Sets the thread using the AddressOf the subroutine where
         // the thread will start.
         FactorialThread = new System.Threading.Thread(new
            System.Threading.ThreadStart(this.Factorial));
         // Starts the thread.
         FactorialThread.Start();
         break;
      case 2:
         FactorialMinusOneThread = new
            System.Threading.Thread(new
               System.Threading.ThreadStart(this.FactorialMinusOne));
         FactorialMinusOneThread.Start();
         break;
      case 3:
         AddTwoThread = new System.Threading.Thread(new
             System.Threading.ThreadStart(this.AddTwo));
         AddTwoThread.Start();
         break;
      case 4:
         LoopThread = new System.Threading.Thread(new
            System.Threading.ThreadStart(this.RunALoop));
         LoopThread.Start();
         break;
   }
}
```

When a **Thread** object is instantiated, it requires an argument in the form of a **ThreadStart** object. The **ThreadStart** object is a delegate that points to the address of the method where the thread is to begin. A **ThreadStart** object cannot take parameters or pass values, and therefore can only indicate a **void** method. The **ChooseThreads** method you just implemented will receive a value from the program calling it and use that value to determine the appropriate thread to start.

To add the appropriate code to frmCalculations

1. Open the **frmCalculations.cs** file in the Code Editor, then locate `protected void btnFactorial1_Click`.
   a. Comment out the line that calls the **Calculator1.Factorial1** method directly as shown:

```
// Calculator1.Factorial()
```

   b. Add the following line to call the **Calculator1.ChooseThreads** method:

```
// Passes the value 1 to Calculator1, thus directing it to start the
// correct thread.
Calculator1.ChooseThreads(1);
```

2. Make similar modifications to the other button_click subroutines.

   Note Be certain to include the appropriate value for the **Threads** argument.

   When you have finished, your code should look similar to the following:

```
protected void btnFactorial1_Click(object sender, System.EventArgs e)
// Passes the value typed in the txtValue to Calculator.varFact1
{
   Calculator1.varFact1 = int.Parse(txtValue.Text);
   // Disables the btnFactorial1 until this calculation is complete
   btnFactorial1.Enabled = false;
   // Calculator1.Factorial();
   Calculator1.ChooseThreads(1);
}

protected void btnFactorial2_Click(object sender, System.EventArgs e)
{
   Calculator1.varFact2 = int.Parse(txtValue.Text);
   btnFactorial2.Enabled = false;
   // Calculator1.FactorialMinusOne();
   Calculator1.ChooseThreads(2);
}
protected void btnAddTwo_Click(object sender, System.EventArgs e)
{
   Calculator1.varAddTwo = int.Parse(txtValue.Text);
   btnAddTwo.Enabled = false;
   // Calculator1.AddTwo();
   Calculator1.ChooseThreads(3);
}

protected void btnRunLoops_Click(object sender, System.EventArgs e)
{
   Calculator1.varLoopValue = int.Parse(txtValue.Text);
   btnRunLoops.Enabled = false;
   // Lets the user know that a loop is running
   lblRunLoops.Text = "Looping";
   // Calculator1.RunALoop();
   Calculator1.ChooseThreads(4);
}
```

Marshalling Calls to Controls

You will now facilitate updating the display on the form. Because controls are always owned by the main thread of execution, any call to a control from a subordinate thread requires a *marshalling* call. Marshalling is the act of moving a call across thread boundaries, and is very expensive in terms of resources. To minimize the amount of marshalling that needs to occur, and to be sure that your calls are handled in a thread-safe manner, you will use the Control.BeginInvoke Method to invoke methods on the main thread of execution, thereby minimizing the amount of cross-thread-boundary marshalling that must occur. This kind of call is necessary when calling methods that manipulate controls. For details, see Manipulating Controls From Threads.

To create the control-invoking procedures

1. Open the code editor for **frmCalculations**. In the declarations section, add the following code:

```
public delegate void FHandler(double Value, double Calculations);
public delegate void A2Handler(int Value, double Calculations);
public delegate void LDHandler(double Calculations, int Count);
```

   Invoke and **BeginInvoke** require a delegate to the appropriate method as an argument. These lines declare the delegate signatures that will be used by **BeginInvoke** to invoke the appropriate methods.

2. Add the following empty methods to your code.

```
public void FactHandler(double Value, double Calculations)
{
}
public void Fact1Handler(double Value, double Calculations)
{
}
public void Add2Handler(int Value, double Calculations)
{
}
public void LDoneHandler(double Calculations, int Count)
{
}
```

3. From the **Edit** menu, use **Cut** and **Paste** to cut all the code from the method `FactorialHandler` and paste it into `FactHandler`.
4. Repeat the previous step for FactorialMinusHandler and Fact1Handler, AddTwoHandler and Add2Handler, and LoopDoneHandler and LDoneHandler.

   When finished, there should be no code remaining in `FactorialHandler`, `Factorial1Handler`, `AddTwoHandler`, and `LoopDoneHandler`, and all the code these used to contain should have been moved to the appropriate new methods.

5. Call the **BeginInvoke** method to invoke the methods asynchronously. You can call **BeginInvoke** from either your form (**this**) or any of the controls on the form.

   When complete, your code should look similar to the following:

```
protected void FactorialHandler(double Value, double Calculations)
{
   // BeginInvoke causes asynchronous execution to begin at the address
   // specified by the delegate. Simply put, it transfers execution of
   // this method back to the main thread. Any parameters required by
   // the method contained at the delegate are wrapped in an object and
   // passed.
   this.BeginInvoke(new FHandler(FactHandler), new Object[]
      {Value, Calculations});
}
protected void FactorialMinusHandler(double Value, double Calculations)
{
   this.BeginInvoke(new FHandler(Fact1Handler), new Object []
      {Value, Calculations});
}

protected void AddTwoHandler(int Value, double Calculations)
{
   this.BeginInvoke(new A2Handler(Add2Handler), new Object[]
      {Value, Calculations});
}

protected void LoopDoneHandler(double Calculations, int Count)
{
   this.BeginInvoke(new LDHandler(LDoneHandler), new Object[]
      {Calculations, Count});
}
```

It may seem as though the event handler is simply making a call to the next method. The event handler is actually causing a method to be invoked on the main thread of operation. This approach saves on calls across thread boundaries and allows your multithreaded applications to run efficiently and without fear of causing lockup. For details on working with controls in

a multithreaded environment, see Manipulating Controls From Threads

6. Save your work.
7. Test your solution by choosing **Start** from the **Debug** menu.
   a. Type **10000000** in the text box and click **Run A Loop**.

      "Looping" is displayed in the label beneath this button. This loop should take a significant amount of time to run. If it completes too early, adjust the size of the number accordingly.

   b. In rapid succession, click all three buttons that are still enabled. You will find that all buttons respond to your input. The label beneath **Add Two** should be the first to display a result. Results will later be displayed in the labels beneath the factorial buttons. These results evaluate to infinity, as the number returned by a 10,000,000 factorial is too large for a double-precision variable to contain. Finally, after an additional delay, results are returned beneath the **Run A Loop** button.

      As you just observed, four separate sets of calculations were performed simultaneously upon four separate threads. The user interface remained responsive to input, and results were returned after each thread completed.

Coordinating Your Threads

An experienced user of multithreaded applications may perceive a subtle flaw with the code as typed. Recall the lines of code from each calculation-performing subroutine in **Calculator.cs**:

```
varTotalCalculations += 1;
varTotalAsOfNow = varTotalCalculations;
```

These two lines of code increment the public variable **varTotalCalculations** and set the local variable **varTotalAsOfNow** to this value. This value is then returned to **frmCalculations** and displayed in a label control. But is the correct value being returned? If only a single thread of execution is running, the answer is clearly yes. But if multiple threads are running, the answer becomes more uncertain. Each thread has the ability to increment the variable **varTotalCalculations**. It is possible that after one thread increments this variable, but before it copies the value to **varTotalAsOfNow**, another thread could alter the value of this variable by incrementing it. This leads to the possibility that each thread is, in fact, reporting inaccurate results. Visual C# provides the lock Statement to allow synchronization of threads to ensure that each thread always returns an accurate result. The syntax for **lock** is as follows:

```
lock(AnObject)
{
   // Insert code that affects the object.
   // Insert more code that affects the object.
   // Insert more code that affects the object.
// Release the lock.
}
```

When the **lock** block is entered, execution on the specified expression is blocked until the specified thread has an exclusive lock on the object in question. In the example shown above, execution is blocked on `AnObject`. **lock** must be used with an object that returns a reference rather than a value. The execution may then proceed as a block without interference from other threads. A set of statements that execute as a unit are said to be *atomic*. When the `}` is encountered, the expression is freed and the threads are allowed to proceed normally.

To add the lock statement to your application

1. Open **Calculator.cs** in the Code Editor.
2. Locate each instance of the following code:

   ```
   varTotalCalculations += 1;
   varTotalAsOfNow = varTotalCalculations;
   ```

   There should be four instances of this code, one in each calculation method.

3. Modify this code so that it reads as follows:

   ```
   lock(this)
   {
   ```

```
    varTotalCalculations += 1;
    varTotalAsOfNow = varTotalCalculations;
}
```

4. Save your work and test it as in the previous example.

   You may notice a slight impact on the performance of your program. This is because execution of threads stops when an exclusive lock is obtained on your component. Although it ensures accuracy, this approach impedes some of the performance benefits of multiple threads. You should carefully consider the need for locking threads, and implement them only when absolutely necessary.

Creating Threads

The .NET Framework allows you to create multithreaded applications quickly and easily by providing an object-oriented threading model. Creating a new thread is as easy as declaring it and supplying it with a delegate to the method where the thread is to start. When you are ready to begin execution on the thread, call the Thread.Start Method. There are special considerations involved when working with multiple threads of execution. For an overview of techniques involved in working with multiple threads, see Thread-Safe Components.

To create a new thread of execution

1. Declare the thread.

```
' Visual Basic
Dim myThread as System.Threading.Thread

// C#
System.Threading.Thread myThread;
```

2. Instantiate the thread with the appropriate delegate for the starting point of the thread. Use the **AddressOf** operator to create the delegate in Visual Basic, or create a new **ThreadStart** object in C#.

```
' Visual Basic
myThread = New System.Threading.Thread(AddressOf myStartingMethod)

// C#
myThread = new System.Threading.Thread(new
   System.Threading.ThreadStart(myStartingMethod));
```

3. When ready, call the **Thread.Start** method to start the thread.

```
' Visual Basic
myThread.Start()

// C#
myThread.Start();
```

Thread-Safe Components | Coordinating Multiple Threads of Execution | Multithreading in Components

Coordinating Multiple Threads of Execution

In order for your multithreaded components to be thread-safe, you must coordinate access to shared resources. If multiple threads attempt to access a shared resource at the same time, race conditions can result, causing corruption of data. You can avoid race conditions by using locks. For details on thread-safety and race conditions, see Thread-Safe Components.

To create a lock on an object

1. Identify the code that must be executed atomically and the object on which the code will be executed. For details, see Thread-Safe Components
2. Place a lock on that object and enclose your code inside that lock.

   This code will now be executed atomically on the locked object.

```
' Visual Basic
SyncLock MyObject   ' This represents the start of the lock on MyObject.
' Insert code to be executed atomically on MyObject here.
End SyncLock   ' This represents the end of the lock.

// C#
lock (MyObject)
   // All code inside the braces {} is executed with MyObject locked.
{
   // Insert code to be executed atomically on MyObject here.
}
```

Thread-Safe Components

Sharing resources between threads is a frequent necessity in multithreaded programming. Multiple threads may need to access a shared database, for instance, or make updates to a set of system variables. When more than one thread simultaneously competes for access to shared resources, the possibility of a *race condition* occurs. A race condition exists when a thread modifies a resource to an invalid state, and then another thread attempts to access that resource and use it in the invalid state. Consider the following example:

```
' Visual Basic
Public Class WidgetManipulator
Public TotalWidgets as Integer = 0
Public Sub AddWidget()
   TotalWidgets += 1
   Console.WriteLine("Total widgets = " & TotalWidgets.ToString)
End Sub
Public Sub RemoveWidgets()
   TotalWidgets -= 10
End Sub
End Class

// C#
public class WidgetManipulator
{
   public int TotalWidgets = 0;
   public void AddWidget()
   {
      TotalWidgets++;
      Console.WriteLine("Total widgets = " + TotalWidgets.ToString());
   }
   public void RemoveWidgets()
   {
      TotalWidgets -= 10;
   }
}
```

This class exposes two methods. One method, AddWidget, adds 1 to the TotalWidgets field and writes the value to the console. The second method subtracts 10 from the value of TotalWidgets. Consider what would happen if two threads simultaneously attempted to access the same instance of the WidgetManipulator class. One thread might call AddWidget at the same time that the second thread called RemoveWidgets. In that case, the value of `TotalWidgets` could be changed by the second thread before an accurate value could be reported by the first thread. This race condition can cause inaccurate results to be reported and can cause corruption of data.

Preventing Race Conditions by Using Locks

You can protect critical sections of your code from race conditions by employing *locks*. A lock, represented by the Visual Basic keyword SyncLock Statement, or the C# keyword lock Statement, allows a single thread of execution to obtain exclusive execution rights on an object. The following example demonstrates locks:

```
' Visual Basic
SyncLock MyObject
' Insert code that affects MyObject.
End SyncLock

// C#
lock(MyObject)
{
   // Insert code that affects MyObject.
}
```

When a lock is encountered, execution on the object specified (`MyObject` in the previous example) is blocked until the thread can gain exclusive access to the object. When the end of the lock is reached, the lock is freed and execution proceeds normally. You can only obtain a lock on an object that returns a reference. A value type cannot be locked in this fashion.

Disadvantages of Locks

Although using locks will guarantee that multiple threads do not simultaneously access an object, they can cause significant performance degradation. Imagine a program with many different threads running. If each thread needs to use a particular object and has to wait to obtain an exclusive lock on that object before executing, the threads will all cease executing and back up behind one another, causing poor performance. For these reasons, you should only use locks when you have code that must be executed as a unit. For example, you might update multiple resources that were interdependent. Such code is said to be *atomic*. Restricting your locks only to code that must be executed atomically will allow you to write multithreaded components that ensure the safety of your data while still maintaining good performance.

You must also be careful to avoid situations where *deadlocks* might occur. In this case, multiple threads wait for each other to release shared resources. For example, Thread 1 might hold a lock on resource A and is waiting for resource B. Thread 2, on the other hand, might have a lock on resource B and awaits resource A. In such a case, neither thread will be allowed to proceed. The only way to avoid deadlock situations is through careful programming.

Event Logs and Multithreaded Components

Event logs are for keeping track of significant events when an application is running. Using event logs, you can record information that might be useful for troubleshooting or performance analysis. There are additional considerations when logging events with multithreaded components. First, there must be a mechanism to record the identity of the thread logging the message. Second, thread safety must be taken into account when interacting with the event log. The thread attempting to write a message must obtain an exclusive lock on the log in order to avoid race conditions. For an overview of event logs, see Administering Event Logs. For more information on thread safety, see Thread-Safe Components.

To identify each thread, you should set the Thread.Name Property. This property takes and returns a **String** value, and can be used to set a unique identifier for each thread. This value can then be passed to the EventLog.CreateEventSource Method to designate your thread as an *event source* for each thread. When logging events, your thread can set the **Source** property of the event log to its name, thereby ensuring accurate logging of events.

When executing multiple lines of code in a multithreaded environment, it is important that the threads obtain exclusive locks on the event log before executing any code. For example, consider the following lines of code, executed in a multithreaded environment:

```
' Visual Basic
MyEventLog.Source = Threading.Thread.CurrentThread.Name.ToString
EventLog.WriteEntry("What thread did this come from?", "myApplication")

// C#
MyEventLog.Source = System.Threading.Thread.CurrentThread.Name.ToString();
EventLog.WriteEntry("What thread did this come from?", "myApplication");
```

If multiple threads are executing these lines simultaneously, if is possible for one thread to change the EventLog.Source Property of the event log, and for another thread to write a message, after that property had been changed. In order to avoid conditions such as these, you can use the SyncLock Statement (Visual Basic) or **lock** (C#) statement to obtain an exclusive lock on the object before executing code from multiple threads. Using locking, the previous example would now look like the following:

```
' Visual Basic
SyncLock MyEventLog
   MyEventLog.Source = System.Threading.Thread.CurrentThread.Name.ToString
   EventLog.WriteEntry("What thread did this come from?", "myApplication")
End SyncLock

// C#
lock(MyEventLog)
{
   MyEventLog.Source = Threading.Thread.CurrentThread.Name.ToString();
   EventLog.WriteEntry("What thread did this come from?",
      "myApplication");
}
```

You can also use the **Debug** and **Trace** classes to log events that occur in multithreaded applications. These classes are static classes that allow you to send output to the output window, the console window, a text file or event log, or any other of a number of objects. For details, see Tracing and Instrumenting Applications in Visual Basic and Visual C#.

Multithreading in Components | Logging Events for Multithreaded Components

Logging Events for Multithreaded Components

When logging events from multithreaded components, special considerations come into play. You must supply a means of identifying the thread from which the event came. You must also ensure that the threads do not interfere with one another when logging events. For details, see Event Logs and Multithreaded Components.

To use event logs in multithreaded applications

1. Declare and create the event log. For details, see Creating and Removing Custom Event Logs.
2. Set the Thread.Name Property property of each thread to a unique identifier.

```
' Visual Basic
Dim X as Integer
X = 0
Dim MyThread as New Threading.Thread(AddressOf MyMethod)
MyThread.Name = "Thread number " & X.ToString
' Increments X so no other threads will share the same name.
X += 1

// C#
int X;
X = 0;
Thread MyThread = new Thread(new
   ThreadStart(MyMethod));
MyThread.Name = "Thread Number " + X.ToString();
// Increments X so no other threads will share the same name.
X += 1;
```

3. Create a new **Source** for the event log, and set the **Name** to a unique string value that corresponds to the thread. For details on creating a **Source**, see Adding Your Application as a Source of Event Log Entries.

```
' Visual Basic
Imports System.Threading
' Checks to see if there already is a source with the name of the
' thread.
If Not EventLog.SourceExists(Thread.CurrentThread.Name.ToString, _
   "myApplication") Then
   ' Creates a source with the name of the thread
   EventLog.CreateEventSource(Thread.CurrentThread.Name.ToString, _
      "MyApplication")
End If

// C#
// These lines go at the top of the code
using System.Threading;
using System.Diagnostics;
// Checks to see if there already is a source with the name of the
// thread.
if (!EventLog.SourceExists(CurrentThread.Name.ToString()))
   // Creates a source with the name of the thread.
   EventLog.CreateEventSource(CurrentThread.Name.ToString(),
      "MyApplication");
```

4. Set the **Source** property of the event log to the name of the thread and call the **EventLog.WriteEntry** method.

   Note Be sure to obtain an exclusive lock on the event log before proceeding with these operations.

```
' Visual Basic
' Use the SyncLock keyword to obtain an exclusive lock on an object.
```

```
SyncLock MyEventLog
  MyEventLog.Source = Thread.CurrentThread.Name.ToString
  EventLog.WriteEntry(Thread.CurrentThread.Name.ToString, _
     "Error in Widget 42")
End SyncLock

// C#
// Use the lock keyword to obtain an exclusive lock on an object
lock(MyEventLog)
{
  MyEventLog.Source = Thread.CurrentThread.Name.ToString();
  EventLog.WriteEntry(Thread.CurrentThread.Name.ToString(),
     "Error in Widget 42");
}
```

Manipulating Controls from Threads

Multithreading is best suited to running processor-intensive procedures of class modules. Unlike other components, there are issues with directly calling methods in controls from separate threads. Methods that affect controls should be executed only on the thread on which the control was created. Because marshalling calls from one thread and sending them across thread boundaries to another is very expensive in terms of system resources, you should avoid repeatedly making calls to controls on other threads. At best, direct calls from other threads are expensive, and the performance of your application will suffer. At worst, conditions could occur that cause a deadlock in your application, freezing execution.

However, there might be occasions when you want to call methods of controls from your threads. For example, you might call a method that disables a button or updates a display on a form in response to action taken by a thread. The .NET Framework provides methods that are safe to call from any thread for invoking methods that interact with controls owned by other threads. The **Control.Invoke** method allows for the synchronous execution of methods on controls, whereas the **Control.BeginInvoke** method initiates asynchronous execution. To use these methods, you must declare a delegate with the same signature as the method you will be invoking. Then you can call the **Invoke** or **BeginInvoke** method of any control on the form by supplying the appropriate delegate to the method you want to call. Any required parameters are wrapped in an **Object** and transmitted to the method.

To invoke methods involving controls owned by other threads

1. Declare a delegate with a signature identical to the method you want to invoke.

   The following example shows how to declare a delegate with **Integer** and **String** parameters.

   ```
   ' Visual Basic
   Public Delegate Sub myDelegate(ByVal anInteger as Integer, ByVal _
      aString as String)

   // C#
   public delegate void myDelegate(int anInteger, string aString);
   ```

2. Use any control to invoke methods that manipulate controls owned by other threads.

   Note Parameters (if any) required by the method can be supplied inside an **Object**.

   - If you want to invoke methods synchronously, call the Control.Invoke Method.

     ```
     ' Visual Basic
     Label1.Invoke(New myDelegate(AddressOf myMethod), New _
        Object() {1, "This is the string"})

     // C#
     Label1.Invoke(new myDelegate(myMethod), new Object[] {1,
        "This is the string"});
     ```

   - If you want to invoke methods asynchronously, call the Control.BeginInvoke Method.

     ```
     ' Visual Basic
     Label1.BeginInvoke(New myDelegate(AddressOf myMethod), _
        New Object() {1, "This is the string"})

     // C#
     Label1.BeginInvoke(new myDelegate(myMethod), new
     Object[] {1, "This is the string"});
     ```

Displaying Forms from Components

Although most components do not have visual interfaces, there are times when it may be useful for a user to interact visually with a component. For example, a component that represents a bank account might display a specialized alert form when the account is overdrawn. These functions should remain constant in the component and not depend on the client application. Because forms are classes, it is easy to create an instance of the form, and then display it through your component.

There are two approaches you can use to create a form:

- Create the form outside your component, which allows you to use a designer to create the look and feel of the form.
- Make the form a nested class within your component. An advantage to this approach is that the form is always a part of your component, and you have control over how it is used and exposed. The chief disadvantage, however, is that you will be unable to use a designer with your form, and will have to design it all by hand coding.

To display a form from your component

1. Create the Windows Form you want to display from your component. For details, see Adding Windows Forms to a Project.
2. If the form you want to display is not in the same project as your component, you must create a reference to the project that contains your form by right-clicking **References** in **Solution Explorer** and choosing **Add Reference**. For details, see Adding and Removing References.
3. Declare a local variable as a new instance of the form. For example, if your form was called MyForm, your code would look like the following:

```
' Visual Basic
Dim AFormInstance as New MyForm

// C#
MyForm AFormInstance = new MyForm();
```

4. Call the **Show**, **ShowDialog**, and **Hide** methods of your form to control display, as is shown in the following examples:

```
' Visual Basic
AFormInstance.Show
' Displays the form.
AFormInstance.ShowDialog
' Displays the form and waits for user interaction before continuing.
AFormInstance.Hide
' Hides the form.

// C#
// Displays the form.
AFormInstance.Show();
// Displays the form and waits for user interaction before continuing.
AFormInstance.ShowDialog();
// Hides the form.
AFormInstance.Hide();
```

Code Libraries

Code libraries are convenient ways to package and reuse components. They provide a portable way to encapsulate code in a single file, allow for inheritance and modification of these files, and permit distribution of discrete units of functionality. You can combine components from many different projects into a single code library. For example, you might choose a custom control from one project, a component from another project, and a form from yet another project, and put them all into your code library. You can also customize the library for special purposes. The only limitation is that all files in a single code library must be written in the same language.

A code library is basically an assembly that compiles to a DLL. For more information, see Components and Assemblies.

One of the features of the .NET Framework is the common language specification (CLS). The common language runtime compiles all code written in a CLS-compliant language to the same kind of intermediate code — MSIL. This means that code libraries written in any CLS-compliant language will be accessible from all other languages that support the common language specification. Therefore, a code library written in Visual Basic, for instance, can be used in an application written in C#, C++, or any other CLS-compliant language.

When designing your components and code libraries, it is important to keep in mind that some languages do not support optional parameters. If you think a language that does not support optional parameters may use your code library, then you should take into account that all parameters will have to be supplied for any methods that are called. One way to ensure that a method can be called with any number of optional parameters is to provide multiple overloads of that method. For more information, see Method Implementation in Components.

The access level of the component in your code library will directly determine how these components can be used by the client application. Client components can only access public components. Components marked **Friend** (**internal** in C#) are accessible only to other members of the code library. Private and protected components cannot be accessed from outside the class, (although **Protected** classes can be accessed by derived classes; for more information, see Access Modifiers).

Visual Basic allows for the implementation of modules. If you are implementing modules for distribution in a code library, it is important to realize that other programming languages that don't support modules will see modules as classes containing only shared members. Therefore, other languages will need to use the name of the module as a qualifier to access the members of the module. Accurate documentation of your code library will help prevent problems.

If you plan to make your code library available to more than one application at a time, you might want to install the assembly into the global assembly cache. For a discussion of issues involved in this, see
Working with Assemblies and the Global Assembly Cache.

If you plan to make your code library available to COM clients, there are additional considerations to take into account. For more information, see Exposing .NET Framework Components to COM.

See Also

Creating Code Libraries

Creating Code Libraries

Code libraries allow you to package several related, useful components into a single portable file. This file can then be used to develop other applications, or as a base for inheritance for other components. For more information, see Code Libraries.

To create a code library

1. Create a new **Class Library** project.

   > **Note** The Class Library template is not available in the Standard Edition of Visual Basic .NET. For more information, see Visual Basic Standard Edition Features.

   Two files are created: a default component file and the assembly manifest (AssemblyInfo.vb or AssemblyInfo.cs file), which contains metadata about the code library. For more information, see Assembly Manifest.

2. If you want to write any new code for your library:
   a. From the **Project** menu, choose **Add New Item** to add the appropriate new item (control, component, class, and so on).
   b. Write the appropriate code.
3. From the **Project** menu, choose **Add Existing Item** to add a preexisting item to your code library.
4. Browse to the appropriate **.vb** or **.cs** file and double-click the file to add it.
5. Build the solution, which will be a **.dll** file when compiled.
6. If you want to make your code library available to more than one client application at a time, you may want to install it to the global assembly cache. For more information, see Working with Assemblies and the Global Assembly Cache.
7. If you plan to make your code library available to COM clients, there are additional considerations to take into account. For more information, see Exposing .NET Framework Components to COM.
8. Package and deploy your code library. Because your library is not a freestanding application, it would be packaged as a merge module. For more information, see Creating or Adding a Merge Module Project.

Components and Containers

Components are hosted by *containers*. A container is a specialized collection class that allows you to track your components, and manages the interaction of your components with other components and the external application environment. The following topics provide information on component-container interaction and describe how to use them in your applications.

In This Section

Containers, Sites, and Components
Provides information on components, sites, containers, and how they interact.
Creating Component Containers
Describes how to create a container for components.
Extending Component Containers
Details how to extend component containers to implement custom functionality.
Communication Between Containers and Components
Describes how a component interacts with its container.

Visual Basic Code Example Topics
Lists quickstart-like code examples that help you perform common tasks in Visual Basic .NET.

Containers, Sites, and Components

A container is a specialized collection object that provides logical containment for one or more components. Containers manage the interaction of the components with each other, as well as with the external application environment, by providing an implementation of the **ISite** interface through which interactions can take place. The container allows tracking of your components on a first-in, first-out basis, and allows you to refer to your components by an index. The container also provides for a means of common disposal of your components when you no longer have need for them.

Containment refers to logical containment, not visual or physical containment. The container encapsulates one or more components and provides a wrapper through which clients may interact. The container allows you to add and remove components via the following syntax:

```
' Visual Basic
Imports System.ComponentModel
Dim myComponent As New Component()
Dim myContainer As New Container()
myContainer.Add(myComponent)
myContainer.Remove(myComponent)

// C#
using System.ComponentModel;
Component myComponent = new Component();
Container myContainer = new Container();
myContainer.Add(myComponent);
myContainer.Remove(myComponent);
```

A component container will either be an instance of the **Container** class, or an implementation of the **IContainer** interface. **Container** is the reference implementation of this interface.

Specifying a Component Name

You can also specify a name for your component within the container. This name must be unique within the container, and is specified using the **Add** method.

```
' Visual Basic
Dim myComponent As New Component()
Dim myContainer As New Container()
MyContainer.Add(myComponent, "ThisComponent")

// C#
Component myComponent = new Component();
Container myContainer = new Container();
myContainer.Add(myComponent, "ThisComponent");
```

Managing Resources and Extending Containers

Containers provide a central means of managing the resources associated with your components. When the **Container.Dispose** method is called, the container automatically calls the **Dispose** method of all the contained components, thereby ensuring that resources are released promptly.

Containers are extensible. You can create your own class that inherits from **System.ComponentModel.Container** that incorporates custom functionality. For example, you might create a container that enforced rules that govern which components may be added to the container, as is shown in the following example:

```
' Visual Basic
Public Class MyContainer
   Inherits Container
   Public Overloads Overrides Sub Add(ByVal component As IComponent)
      ' Checks to see if the component is allowed to join this container.
      If TypeOf component Is Widget Then
         ' Calls the Add method of the base class, and adds the component.
         MyBase.Add(component)
      Else
```

```
         ' If the component is not allowed, an exception is thrown.
         Throw New NonWidgetException()
      End If
   End Sub
End Class

// C#
class MyContainer : Container
{
   public override void Add(IComponent component)
   {
      // Checks to see if the component is allowed to join this container.
      if (component is Widget)
      {
         base.Add(component);
      }
      else
      {
         throw new NonWidgetException();
      }
   }
}
```

The previous example creates a new container class that is able to enforce a rule about which components are able to join the container. If a component is not of the specified class (in this case, Widget), then an exception is thrown.

When a component is added to a container, the container creates a **Site** for it. This is an implementation of the **ISite** interface that is exposed through the component's **Site** property. Communication by a component with its host container is accomplished via the component's **Site** property. This property represents the logical site of the component, and is hosted by the container. A component that is not contained in a container returns a **null** reference for its **Site** property. The **Site** property allows you to obtain a reference to the container interface through the **Site.Container** property, or a reference to the component interface being hosted through the **Site.Component** property.

```
' Visual Basic
Dim myComponent As New Component
Dim myContainer As New Container
myContainer.Add(myComponent)
Dim myIComponent as IComponent
Dim myIContainer as IContainer
myIComponent = myComponent.Site.Component
myIContainer = myComponent.Site.Container
' These two messages display True.
MessageBox.Show("Are the components equal? " & _
   myComponent.Equals(myIComponent).ToString)
MessageBox.Show("Are the containers equal? " & _
   myContainer.Equals(myIContainer).ToString)

// C#
Component myComponent = new Component();
Container myContainer = new Container();
myContainer.Add(myComponent);
IComponent myIComponent;
IContainer myIContainer;
myIComponent = myComponent.Site.Component;
myIContainer = myComponent.Site.Container;
MessageBox.Show("Are the components equal? " +
   myComponent.Equals(myIComponent).ToString());
MessageBox.Show("Are the containers equal? " +
   myContainer.Equals(myIContainer).ToString());
```

Both of these properties return only the interface associated with these objects, not a reference to the objects themselves. Note that the component also has a **Container** property that returns the same interface as **Site.Container**. This property is provided by through the **Site** and can be thought of as a shortcut.

If you assign a name to your component using the **Add** method, the name can be retrieved via the **Site.Name** property. If the container has a service object associated with it, a reference to that object can be obtained by the component via the

Site.GetService method.

Communication Between Containers and Components | Creating Component Containers | Extending Component Containers

Creating Component Containers

A component container is a specialized class that acts as a means of organizing and containing components. Through a container you can track your components, communicate with them via the **Site** that hosts the component, and provide a means of common disposal after they are no longer needed. For details, see Containers, Sites, and Components.

To create a component container

1. Declare a variable of the type **System.ComponentModel.Container**, or any class that implements the **IContainer** interface.

```
' Visual Basic
Dim myContainer as System.ComponentModel.Container

//C#
System.ComponentModel.Container myContainer;
```

2. Create an instance of the container class in your variable.

```
' Visual Basic
myContainer = New System.ComponentModel.Container()

// C#
myContainer = new System.ComponentModel.Container();
```

3. Call the **Container.Add** and **Container.Remove** methods to add and remove components to and from your container.

```
' Visual Basic
myContainer.Add(myComponent)
myContainer.Remove(myComponent)

// C#
myContainer.Add(myComponent);
myContainer.Remove(myComponent);
```

See Also

Containers, Sites, and Components | Communication Between Containers and Components | Extending Component Containers | Container Class

Extending Component Containers

Component containers are completely extensible. You can inherit from the **System.ComponentModel.Container** class and add properties or methods, add custom functionality to enforce rules, override base methods, or any other custom functionality you want your container to incorporate. For details on containers and extending containers, see Containers, Sites, and Components.

You extend a **Container** as you would extend any base class. You create a class that inherits the properties of the base class, override any base methods that you want to extend, and add any additional properties or methods that you need. You can then use your new class as you would a standard **Container** and use any of the new functionality you have encoded.

To extend the Container base class

1. Declare a new class that inherits from the **System.ComponentModel.Container** class.

```
' Visual Basic
Public Class myContainer
   Inherits System.ComponentModel.Container
End Class

// C#
class myContainer: System.ComponentModel.Container
{
}
```

2. Override any base-class methods to add additional functionality. The following example shows how to override the **Add** method.

   Note The **Container** actually has two overloads of **Add**, and in this example, you would want to provide an override of each.

```
' Visual Basic
' Because Add is overloaded, this line includes the Overloads keyword.
Public Overloads Overrides Sub Add(ByVal component As _
   System.ComponentModel.IComponent)
   ' Determines if the component can be added to the container.
   If TypeOf component Is Widget Then
      ' Calls the base Add function to add the component.
      MyBase.Add(component)
   Else
      ' Throws an exception.
      Throw New NonWidgetException()
   End If
End Sub

// C#
public override void Add(System.ComponentModel.IComponent component)
{
   if (component is Widget)
      base.Add(component);
   else
   {
      throw(new NonWidgetException());
   }
}
```

3. Add any new properties or methods you want your new container to incorporate. For details, see Class Properties, Fields, and Methods.

See Also

Communication Between Containers and Components

A container is a nexus for communication between the client application and the components it contains. An application may obtain references to components within the container without knowing the actual name or identity of the component. The component may also interact with the client application through the container in a variety of ways.

The container object exposes the components it contains through its **Components** property. This property is an indexed property that returns an **IComponent** reference object. Components are tracked on a first-in, first-out basis, and are accessible through the index using the following syntax:

```
' Visual Basic
Imports System.ComponentModel
Dim MyContainer As Container
Dim xComponent as IComponent
xComponent = MyContainer.Components(0)

// C#
using System.ComponentModel;
Container MyContainer = new Container();
IComponent xComponent;
xComponent = MyContainer.Components[0];
```

Components may be added to a container with or without a name. If you know the name of the component you are referring to, you may also get the reference through the container using that name, as shown in the following example:

```
' Visual Basic
xComponent = MyContainer.Components("myComponent")

// C#
xComponent = MyContainer.Components["myComponent"];
```

Note that the **Components** property returns an **IComponent** reference, and will not allow you to access methods and properties of the component that are not implemented by that interface.

The component communicates with the container primarily through its **Site** property. Through **Site**, the component can obtain reference to the **IContainer** interface implemented by the container, as shown below:

```
' Visual Basic
Dim myComponent As New Component()
Dim myIContainer as IContainer
myIContainer = myComponent.Site.Container

// C#
Component myComponent = new Component();
IContainer myIContainer;
myIContainer = myComponent.Site.Container;
```

The same reference is also returned by the **Component.Container** property. This can be thought of as a shortcut: The reference is still provided through the **Site** object, but not explicitly in this case.

The component can also get services from the container (if they are supplied) by calling IServiceProvider.GetService Method. This method returns an object of the specified type, as shown below:

```
' Visual Basic
Dim myComponent As Component
Dim myWidget As Widget
Dim serviceObject As Object
' This returns an object of type Widget that is supplied by the container.
serviceObject = myComponent.Site.GetService(GetType(Widget))
myWidget = CType(serviceObject, Widget)

// C#
Component myComponent = new Component();
```

```
Widget myWidget;
object serviceObject;
// This returns an object of type Widget that is supplied by the container.
serviceObject = myComponent.Site.GetService(System.Type.GetType("CommunicateCS.Widget"));
myWidget = (Widget)serviceObject;
```

In order to receive an object via **Site.GetService**, it must be implemented in an inherited container class. The **GetService** method of the **Container** class should be overridden and code to supply the service object implemented.

Containers, Sites, and Components | Creating Component Containers | Extending Component Containers

Components that Contain Other Components

An object model defines a hierarchy of objects that gives structure to an object-based program. By defining the relationships between objects that are part of the program, an object model organizes the objects in a way that makes programming easier.

The public object model of a component is especially important, because all the programmers who employ the component as part of their applications use it.

Users who are not new to object-oriented programming might be used to seeing *class hierarchies*. A class hierarchy describes *inheritance*. That is, it shows how objects are derived from simpler objects, inheriting their behavior. By contrast, object models are hierarchies that describe *containment*. That is, they show how complex objects, such as the **TabControl** contain collections of other objects, such as the **TabPages** collection.

The following topics on object models for components provide information about designing and implementing your object model.

In This Section

Component Object-Model Recommendations
Recommends practices for designing and implementing object models in your component.
Complex Components
Describes what nested classes are and how to implement them.
Properties and Collections in Object Models
Demonstrates how to expose subordinate objects using properties and collections.
Collection Properties
Provides an in-depth discussion of how to use collections to expose collections of subordinate objects.
Walkthrough: Creating Your Own Collection Class
Provides step-by-step instructions for implementing your own strongly-typed collection class.

Component Object-Model Recommendations

When designing your component, you should consider how extensive an object model your component needs. Some components — for example, an inherited control — might not need to contain any objects, and would therefore not need an object model. On the other hand, an extremely complex component might need to manage thousand of contained objects. Here are some general recommendations to keep in mind when designing your component object models.

- When possible, expose contained objects as properties. This allows you to control access to the contained objects and validate interactions with contained objects.
- If your object needs to work with and expose an indefinite number of contained objects, implement a collection property. For details, see Collection Properties.
- If your object needs to work with and expose small, defined numbers of contained objects, implement them each as properties.
- If you do not want client applications to be able to use contained objects, set them as **Friend** (**internal** in C#) or **Private**. In these cases, you might want to consider using nested classes. For details, see Nested Classes in Components.
- When implementing a collection property, you must determine how much collection functionality you want to expose to client applications. If you want to expose relatively little functionality, wrap your collection in a property and expose only selected members. If you want to expose a greater amount of functionality, consider creating a custom collection class and exposing the collection directly as a property. For details about these two approaches, see Collection Properties.
- Keep it simple. Generally speaking, a simpler implementation will be faster. If accessing an item involves a series of nested references and function calls, performance will suffer and your component will be more difficult to use. Simple, well-thought-out object models make your component easy for developers and client applications to use alike.

Complex Components

Complex components consist of a lot of subordinate objects. For example, a graphics-rendering component might consist of brushes, pens, colors, and a variety of contained objects.

These contained objects may come from different sources. Your component might instantiate and contain classes that are part of the assembly in which it resides. They may call upon other assemblies, such as those in the .NET Framework, to provide the classes that they need to fulfill their functions. Or they may have the source code for these contained objects nested within their own code.

Nested classes are classes that are completely contained within another class declaration. They are useful for providing objects that are required by a particular class to function, but have no stand-alone functionality.

The following topics provide information on designing and implementing nested classes.

Nested Classes in Components

Many components are fairly simple. They might consist of a single class with a simple object model or no object model. Other components are more complex, and might need to contain and manage a large number of subordinate objects. Nested classes are one way for complex components to contain and manage the objects they need.

A nested class is a class that is fully enclosed within another class declaration. For example, a nested class and an enclosing class might look like the following example:

```
' Visual Basic
' This is the enclosing class, whose class declaration contains the nested
' class.
Public Class EnclosingClass
   ' This is the nested class. Its class declaration is fully contained
   ' within the enclosing class.
   Public Class NestedClass
   ' Insert code to implement NestedClass.
   End Class
' Insert code to implement EnclosingClass.
End Class

// C#
// This is the enclosing class, whose class declaration contains the
// nested class.
public class EnclosingClass
{
   // This is the nested class. Its class declaration is fully contained
   // within the enclosing class.
   public class NestedClass
   {
      // Insert code to implement NestedClass.
   }
   // Insert code to implement EnclosingClass.
}
```

In this example, the class declaration for NestedClass is fully contained by the class declaration of EnclosingClass.

As a result of being contained within the enclosing class, the nested class gains a certain level of protection. Unless you use the **Imports** (**using** in C#) statement, all references to the nested class must be qualified with the name of the containing class. For example, to instantiate the nested class in the previous example, you would have to use the following syntax:

```
' Visual Basic
Dim aClass as New EnclosingClass.NestedClass()

// C#
EnclosingClass.NestedClass aClass = new EnclosingClass.NestedClass();
```

The access level of the nested class is implicitly at least the access level of the enclosing class. Even if the nested class is **Public**, if the enclosing class is **Friend** (**internal** in C#), then only members of the assembly will be able to access the nested class, and if the enclosing class is **Private**, then the nested class will be unavailable to all callers except the enclosing class.

Assuming a **Public** enclosing class, the access level of the nested classes pretty much follows the same rules as for access of unnested classes. Friend classes are available to members of the assembly, but not external clients. **Private** classes are available to the enclosing class, other nested classes within the enclosing class, and any classes nested within other nested classes.

Nested classes are useful when an object will logically contain subordinate objects, but other objects would have use for those objects. An example might be a Wheel class. This could be a class that clients could create and use wherever a wheel might be needed in their application. But except in the most primitive implementations, a wheel is not just a single object, but is composed of several subordinate objects, each of which build the wheel. A wheel might have a Rim object, Tire object, Spoke objects and other objects, without which the wheel could not function. But the average user would have no need to create a spoke, or a rim, or a bearing — all he's interested in is the wheel.

In a case like this, it makes sense for the Wheel class to contain the implementation for all of its subordinate classes. This way, the wheel can create and manage any contained objects it may need while conveniently hiding the details of this implementation

from the client. Those subordinate objects the client might reasonably need to have contact with now and again (for example, a Tire object) can be exposed as part of the public object model, and those that a client should never see (for example, a Bearings collection) could be declared private and hidden.

Components that Contain Other Components

Recommendations on Nested Classes in Components

The use of nested classes in your components is a powerful and convenient way to supply subordinate objects that your component might use. Nested classes allow your component to create and use objects without making them accessible or creatable by external users. Overuse of nested classes, however, can make your components difficult to work with and maintain. Here are some design recommendations that will help you to use nested classes in your components.

- If your class is logically contained by another class, but has no stand-alone significance, implement it as a nested class. An example of this might be a Bearing class nested in a Wheel class. The Wheel object might need Bearing objects, but a client application would never have a need to create Bearing objects independent of a Wheel object.
- If members of your class need to access private member variables of the object containing it, you can implement it as a nested class. For example, a Wheel object might have a private Radius field. If a Spoke object needs to access the Radius field, it can always have that access if it is implemented as a nested class.
- If a class needs to implement an interface for interaction with other components, you can create an implementation of that interface as a nested class and expose an instance of the class as an interface property.
- If your component will need to use one of several different subtypes of a contained object, but the subtype will not be known until run time, you can implement each subtype as a nested class as opposed to implementing all possible subtypes within a single class. When used with Just-In-Time compilation, nesting classes improves program performance because only the required type is compiled.
- If other classes will reasonably need access, or will want to collect or contain your class, do not implement it as a nested class. A class that is accessed by several other classes should stand alone.
- In general, do not implement public nested classes. Nested classes should primarily be for the internal use of the containing class. If you do implement a public nested class, it should be a class that logically belongs to the containing type, and is used infrequently. An exception would be if an instance of the nested class was exposed as a property on the containing class. For instance, a Wheel object might have a SpokesCollection nested class, an instance of which might be exposed as the SpokesCollection property.

Implementing Nested Classes

If you are developing a complex component, you may need to implement nested classes. Nested classes are classes where the class declaration is fully contained within the class declaration of another class, and are useful for developing object models in your component. For more information on how they can be used, see Nested Classes in Components and Recommendations on Nested Classes in Components.

Implementing nested classes is a trivial matter. Once the class declaration is fully enclosed within another class declaration, the class is considered nested and can only be accessed through the containing class.

To implement a nested class within a containing class

- Within the class declaration of the containing class, add the class declaration for the nested class. If you have already written the code for the nested class, you may cut and paste it into the class declaration.

  The following example shows how to implement a nested class:

```
' Visual Basic
' This class contains the nested class.
Public Class TheClass
   ' This class is the nested class.
   Private Class NestedClass
   ' Insert code to implement the nested class.
   End Class
   ' Insert code to implement TheClass.
End Class

// C#
// This class contains the nested class.
public class TheClass
{
   // This is the nested class
   private class NestedClass
   {
      // Insert code to implement NestedClass.
   }
   // Insert code to implement TheClass.
}
```

Properties and Collections in Object Models

Objects in a hierarchy are linked together by object properties — that is, properties that return references to objects. An object that contains other objects will have properties that return either references to the objects themselves, or references to collections of objects.

For example, consider a Bicycle object that represents a bicycle. The Bicycle object would have a Frame property that returned a reference to its Frame object. The Frame object would have a FrontWheel and BackWheel property, each of which would return a Wheel object. The Wheel object would have a Rim property that would return a Rim object, and a Spokes property that would return a Spokes collection object. The Spokes collection would contain the Spoke objects.

It makes sense to organize the object model for a Bicycle object in this way. A Bicycle needs a Frame, a Frame needs Wheels, and Wheels need Spokes. A functioning bicycle cannot exist without these objects, and they are components that make up the bicycle itself. A Bicycle object might interact with a Rider object, but would not contain a Rider object, because a perfectly good, functional bicycle can exist independent of a rider. The object properties represent components that provide a necessary functional part of the overall object.

You may also have dependent objects that are used internally by classes in your component, and which you do not want to provide to users of your component. For example, both the Frame and Wheel objects might have collections of Bearing objects, but there may be no reason to expose the Bearings object, or the collections containing it, for manipulation by client applications. You can implement these as **Private** nested classes. For details, see Nested Classes in Components.

The Simple Way to Link Dependent Objects

Frequently it makes sense for a complex object to have only one instance of a dependent object. For example, a Bicycle object only needs one Frame object. In this case, you can link the Frame object to a simple property of the complex object:

```
' Visual Basic
Private mFrame As New Frame()
Public ReadOnly Property MyFrame() as Frame
   Get
      Return mFrame
   End Get
End Property

// C#
private Frame mFrame = new Frame();
public Frame MyFrame
{
   get
   {
      return mFrame;
   }
}
```

It is important to implement such properties as shown above, using a read-only property procedure, rather than simply declaring a public module-level variable, as shown below.

```
' Visual Basic
Public myFrame As Frame

// C#
public frame myFrame;
```

With the second implementation, a user of your component might set the Frame property to Nothing. If there are no other references to the Frame object, it will be destroyed.

Linking a Fixed Number of Objects

Even when a complex object contains more than one instance of a dependent object, it may make more sense to implement the linkage with properties instead of with a collection. For example, a Bicycle object always has two wheels:

```
' Visual Basic
```

```
Private mwhlFront As New Wheel
Private mwhlRear As New Wheel
Public ReadOnly Property FrontWheel() As Wheel
   Get
      Return mwhlFront
   End Get
End Property
Public ReadOnly Property RearWheel() As Wheel
   Get
      Return mwhlRear
   End Get
End Property

// C#
private Wheel mwhlFront = new Wheel();
private Wheel mwhlRear = new Wheel();
private Frame mFrame = new Frame();
public Wheel FrontWheel
{
   get
   {
      return mwhlFront;
   }
}
public Wheel RearWheel
{
   get
   {
      return mwhlRear;
   }
}
```

Using Collections in Your Object Model

When the relationship between two objects in a hierarchy is such that the first object contains an indeterminate number of the second, the easiest way to implement the link is with a collection. A *collection* is an object that contains a set of related objects.

A property exposes a collection of objects by acting as a wrapper around the collection. When the property is accessed, it returns the appropriate member of the collection by taking an indexer as a parameter, using that indexer to access the collection and find the specified object, then converts it (if necessary) to the appropriate type before returning the object.

The .NET Framework provides several different collection classes that can serve as the basis for an object collection property. For details, see Collection Properties.

See Also

Collection Properties | Component Object-Model Recommendations

Collection Properties

When your object model exposes an indeterminate number of objects of a particular type as a property, you will want to provide a collection as part of the implementation of that property. You can choose how to implement that property depending on the kind of functionality you want your property to support.

The .NET Framework supplies several different types of collection classes you can use to track and manage objects in your object model. Additionally, Visual Basic .NET provides the **Collection** class, which can be used to keep track of objects collections that are exposed as properties. If using C#, you should implement collections in your object model by using one of the collection classes provided in the **System.Collections** namespace.

Some of the collection classes in the System.Collections are briefly described below. You can use these classes to implement your collection properties depending on the requirements of your class. For additional information on these classes, consult the appropriate help topic.

- ArrayList Class provides basic enumerable, indexed list of objects.
- BitArray Class manages a compact array of bits (1 and 0).
- CollectionBase Class provides a base class for collections. It is an abstract (MustInherit) class that must have some functionality implemented. For information on how to implement your own collection class, see Walkthrough: Creating Your Own Collection Class.
- Queue Class tracks objects on a first in-first out basis.
- SortedList Class provides a collection that allows you access either by index or by key.
- Stack Class tracks objects on a first in-last out basis.

Simple Collection Properties

The following example shows how to implement a simple collection property using the ArrayList Class.

```
' Visual Basic
Private spokesCollection As New System.Collections.ArrayList
Public ReadOnly Property Spokes() As System.Collections.ArrayList
   Get
      Return spokesCollection
   End Get
End Property

// C#
System.Collections.ArrayList spokesCollection = new
   System.Collections.ArrayList();
System.Collections.ArrayList Spokes
{
   get
   {
      return spokesCollection;
   }
}
```

Robust Collection Properties

Although the previous example is a very simple and easy way to provide a collection property, it is not very robust. There are several problems with this implementation as a collection property. First, it allows clients of your application to access all the functionality contained by the collection. You may not want other users to be able to remove objects, for instance, or to add new items. Second, it is not strongly typed. Any kind of object may be added to your spokes collection, as shown above.

The most robust way to address these issues is by creating your own custom collection class by inheriting from **System.Collections.CollectionBase**. This approach allows you to create a collection class that is strongly typed and exposes whatever methods you decide. Creating your own collection class allows you to retain the use of **For Each...Next** with your collections. You can create **Public (public)** methods for public use, **Friend (internal)** methods for use by other objects in your assembly, and **Private (private)** methods for the object's own use. Information on how to create a custom collection class can be found in Walkthrough: Creating Your Own Collection Class.

A less robust, but possibly more convenient way to address these issues is by not directly exposing the collection object, but rather by returning members of the collection. This can be accomplished by wrapping the collection object inside the property

call. Using this method, you are able to retain almost all of the functionality of a collection class (with the exception of being able to use **For Each...Next**), and can control access to all of the methods provided by the collection and enforce type safety. The following example shows how to implement a collection property using the SortedList Class This collection property provides access to members of the collection either by index or by key.

```
' Visual Basic
Private spokesCollection As System.Collections.SortedList
' This is the first of two overloads of the property. This overload allows
' the user to retrieve a Spoke object by specifying an index
Public Overloads ReadOnly Property Spokes(ByVal i As Integer) As Spoke
   Get
      ' CType converts the object reference returned by spokesCollection
      ' to a Spoke object.
      Return CType(spokesCollection(i), Spoke)
   End Get
End Property
' This overload allows the user to retrieve a Spoke object by specifying a ' key
Public Overloads ReadOnly Property Spokes(ByVal key As String) As Spoke
   Get
      ' CType converts the object reference returned by spokesCollection
      ' to a Spoke object.
      Return CType(spokesCollection(key), Spoke)
   End Get
End Property

// C#
private System.Collections.SortedList spokesCollection;
// Because properties in C# cannot accept parameters, we will implement
//  these as methods instead. This is the first of two overloads of the
// method. This overload allows the user to retrieve a Spoke object by
// specifying an index
public Spoke GetSpokeAt(int i)
{
   // returns the appropriate member of the collection, converted to the
   // appropriate type
   return (Spoke)spokesCollection[i];
}

public Spoke GetSpokeAt(string key)
{
   // returns the appropriate member of the collection, converted to the
   // appropriate type
   return (Spoke)spokesCollection[key];
}
```

Exposing Methods in Collection Properties

In the previous example, the methods implemented by the collection itself are inaccessible to external users; only the containing class can **Add** or **Remove** members, or use any of the other collection methods.

You might want to expose one or more of these methods to external users. This is easily accomplished by wrapping the call to the collection method inside a new method. The following example shows how to wrap the spokesCollection object inside a public method, which allows clients to add new Spoke objects to the collection.

```
' Visual Basic
' This example assumes all the code from the previous example is in the same class.
Public Sub AddSpoke(ByVal Key as String)
   Dim aSpoke as New Spoke()
   SpokesCollection.Add(Key, aSpoke)
End Sub
```

```
// C#
public void AddSpoke(string Key)
{
   Spoke aSpoke = new Spoke();
```

```
    spokesCollection.Add(Key, aSpoke);
}
```

Walkthrough: Creating Your Own Collection Class | System.Collections Namespace | Component Object-Model Recommendations | Properties and Collections in Object models

Walkthrough: Creating Your Own Collection Class

You can create your own collection classes by inheriting from one of the many .NET Framework collection classes and adding code to implement your own custom functionality. In this topic, you will use inheritance to create a simple, strongly typed collection inherited from **CollectionBase**.

The .NET Framework provides several collection-type classes in the **System.Collections** namespace. Some, such as **Stack**, **Queue**, and **Dictionary**, are specialized classes that have been implemented to fulfill specific roles. Others, such as **CollectionBase** and **DictionaryBase**, are **MustInherit (abstract)** classes that have some basic functionality in place, but which leave much of the implementation to the developer.

The **CollectionBase** class already has implementations for the **Clear** method and the **Count** property, and it maintains a **Protected** property called **List**, which it uses for the internal storage and organization. Other methods, such as **Add** and **Remove**, as well as the Item property, require implementation.

In this walkthrough, you use the **CollectionBase** class to create a class called WidgetCollection. This is a collection that accepts only widgets, and exposes its members as Widget types, instead of accepting objects and exposing members as **Object** type. You then implement methods to add widgets to your collection and to remove the widget at a specific index, and you also implement an **Item** property that returns the widget object at the appropriate index.

Creating the Classes

The first step is to create a Widget class to put into your WidgetCollection.

To create the Widget class

1. Open a new Windows Application and name it **WidgetProject**. From the Project menu, choose **Add Class**. In the Add New Item dialog box, name your class **Widget.vb** for Visual Basic and **Widget.cs** for Visual C#.

   The Code Editor for the Widget class opens.

2. Add a public Name variable to your Widget class. Your code should look similar to the following:

```
' Visual Basic
Public Class Widget
   Public Name as String
End Class

// C#
public class Widget
   {
      public string Name;
      public Widget()
      {
      }
   }
```

3. From the File menu, choose **Save All**.

You have now created a Widget class for use with the WidgetCollection class you create next. The Widget class is a simple class, which serves to illustrate how your strongly typed collection will work. The next step is to create the WidgetCollection class.

To create the WidgetCollection class

1. From the Project menu, choose **Add Class**. In the Add New Item dialog box, name your class **WidgetCollection.vb** for Visual Basic and **WidgetCollection.cs** for Visual C#. The code editor for the WidgetCollection class opens.
2. In the code editor, add code to cause the class to inherit from **CollectionBase**, as in this example:

```
' Visual Basic
Public Class WidgetCollection
   Inherits System.Collections.CollectionBase
End Class

// C#
```

```
public class WidgetCollection : System.Collections.CollectionBase
   {
   }
```

3. From the **File** menu, choose **Save All**.

You have now created your WidgetCollection class. Because this class inherits from **CollectionBase**, it already has much of the collection functionality implemented. There is a **Clear** method to clear the collection and a **Count** property that keeps track of the number of current members. Additionally, there is a **Protected** object called **List**, which you use to keep track of your widgets. But there is no **Add** method, no **Remove** method, and no **Item** property. The implementation of these is left up to the developer.

Implementing the Add and Remove Methods

You will now implement the **Add** method so that WidgetCollection will add only Widget objects.

To implement the Add method

1. Add the following code to your WidgetCollection class, beneath the **class** statement in C#, or the **Inherits** statement in Visual Basic:

```
' Restricts to Widget types, items that can be added to the collection.
Public Sub Add(ByVal awidget As Widget)
   ' Invokes Add method of the List object to add a widget.
   List.Add(aWidget)
End Sub

// C#
// Restricts to Widget types, items that can be added to the collection
public void Add(Widget aWidget)
{
   List.Add(aWidget);
}
```

   In this method, you restrict to **Widget** types the items that can be added to the **List** object through the argument taken by the **Add** method. Though the **List** object can accept any type of object, this method prohibits any objects but Widget types from being added, and acts as a "wrapper" around the **List** object.

2. From the **File** menu, choose **Save All.**

You now have a way to add widgets to your collection. You must now implement a way to remove them. You will do this in a manner similar to the way you created the **Add** method, by creating a **Remove** method that accepts an index as an argument and in turn calls the **List.RemoveAt** method.

To implement the Remove method

1. Beneath the `Add` method, add the following code:

```
' Visual Basic
Public Sub Remove(ByVal index as Integer)
   ' Check to see if there is a widget at the supplied index.
   If index > Count - 1 Or index < 0 Then
      ' If no widget exists, a messagebox is shown and the operation is
      ' cancelled.
      System.Windows.Forms.MessageBox.Show("Index not valid!")
   Else
   ' Invokes the RemoveAt method of the List object.
      List.RemoveAt(index)
   End If
End Sub

// C#
public void Remove(int index)
{
```

```
   // Check to see if there is a widget at the supplied index.
   if (index > Count - 1 || index < 0)
      // If no widget exists, a messagebox is shown and the operation
      // is cancelled.
      {
         System.Windows.Forms.MessageBox.Show("Index not valid!");
      }
   else
      {
         List.RemoveAt(index);
      }
}
```

This method accepts an integer value for the index argument. If the value is valid, it is passed to the **RemoveAt** method of the **List** object, thereby removing the item at the indicated index from the collection.

2. From the **File** menu, choose **Save All.**

Implementing the Item Property

You need to implement one final piece in order to complete basic collection functionality, and that is the **Item** property. The **Item** property allows you to obtain a reference to an object in your collection by referring to the index. Since you already have an **Add** method to add members to the collection, **Item** will be a **ReadOnly** property in this demonstration, though it need not be in other contexts. Because C# does not allow properties to have parameters, you will implement **Item** as a method if you are using C#.

To implement the Item property

1. Beneath the `Sub Remove` method, add the following code:

```
' This line declares the Item property as ReadOnly, and
' declares that it will return a Widget object.
Public ReadOnly Property Item(ByVal index as Integer) As Widget
   Get
      ' The appropriate item is retrieved from the List object and
      ' explicitly cast to the Widget type, then returned to the
      ' caller.
      Return CType(List.Item(index), Widget)
   End Get
End Property

// C#
public Widget Item(int Index)
{
   // The appropriate item is retrieved from the List object and
   // explicitly cast to the Widget type, then returned to the
   // caller.
   return (Widget) List[Index];
}
```

In collections, the syntax `Collection.Item(0)` and `Collection(0)` are frequently interchangable. If you want to your collection to support this syntax, you should make the Item property the Default property (for Visual Basic) or implement an indexer (in C#). For more information, see Default Properties for Your Components.

2. From the File menu, choose **Save All**.

You have now implemented basic collection functionality in your class. You have implemented methods to add and remove widgets from the collection, and you have implemented a property that returns a Widget reference to the appropriate item. In this next section, you will test your WidgetCollection class.

Testing the Project

Now that your WidgetCollection class is complete, it is time to test the functionality. To do this, you will create a simple Windows application that will add, remove, and loop through the widgets in your collection.

To create the test project

1. In Solution Explorer, right-click **Form1**, then click **View Designer** on the shortcut menu.

   The designer for Form1 opens.

2. Using the Toolbox, add two **Label** controls, two **TextBox** controls, and three **Button** controls to Form1.
3. Set the properties as follows:

Control	Property	Value
Label1	**Text**	"Widget Name"
Label2	**Text**	"Widget Index"
TextBox1	**Text**	""
TextBox2	**Text**	""
Button1	**Text**	"Add a Widget"
Button2	**Text**	"Remove a Widget"
Button3	**Text**	"Review Widgets"

   In the design of your form, Label1 should label TextBox1, and Label2 should Label TextBox2.

4. In the Form Designer, right-click WidgetTest and choose **View Code**.

   The Code Editor for WidgetTest opens.

5. In the Code Editor, locate the line `Inherits` line (Visual Basic) or the `class` line (Visual C#). Immediately beneath it, type the following code:

```
' Visual Basic
' Creates a WidgetCollection object.
Dim myWidgetCollection as New WidgetCollection()

// C#
WidgetCollection myWidgetCollection = new WidgetCollection();
```

6. In the designer, double-click button1, which now reads "Add a Widget".
7. In the **button1_Click** event handler, add code to add a new widget to the collection and set the name of this widget to the value of `textBox1`.

```
' Visual Basic
If textbox1.Text = "" Then
   MessageBox.Show("Please name your widget.")
Else
   ' Declares and instantiates a new widget.
   Dim aWidget as New Widget()
   ' Sets the Name field of the new widget.
   aWidget.Name = textBox1.Text
   ' Adds the new widget to the collection.
   myWidgetCollection.Add(aWidget)
   ' Updates textBox2 with the index of the widget that was added.
   ' The index of a zero-based collection is Count property minus 1.
   textBox2.Text = (myWidgetCollection.Count - 1).ToString()
End If

// C#
if (textBox1.Text == "")
   MessageBox.Show("Please name your widget.");
else
{
   // Declares and instantiates a new widget.
   Widget aWidget = new Widget();
```

```
    aWidget.Name = textBox1.Text;
    // Adds the new widget to the collection
    myWidgetCollection.Add(aWidget);
    // Updates textbox2 with the index of the widget that was added.
    // The index of a zero-based collection is Count property minus 1
    textBox2.Text = (myWidgetCollection.Count -1).ToString();
}
```

8. In the **button2_Click** event handler, add code to remove the widget at the index specified in `textBox2`.

```
' Visual Basic
Try
   myWidgetCollection.Remove(CInt(textBox2.Text))
Catch ex as System.InvalidCastException
   MessageBox.Show("You have attempted to perform an invalid cast")
End Try
// C#
try
{
   myWidgetCollection.Remove(int.Parse(textBox2.Text));
}
catch (System.InvaldiCastException ex)
{
   MessageBox.Show("You have attempted to perform an invalid cast");
}
```

   Note that you while you must provide error handling to catch any **System.InvalidCastException** that might be thrown as the result of an invalid character in the textbox, there is no need to check if a valid value for the index exists in textBox2, because the **WidgetCollection.Remove** method checks this automatically.

9. In the **button3_Click** event handler, write code to cycle through all members of the collection and sequentially display their names in a message box.

```
' Visual Basic
Dim counter as Integer
For counter = 0 to myWidgetCollection.Count - 1
   MessageBox.Show(myWidgetCollection.Item(counter).Name)
Next

// C#
int counter;
for(counter = 0; counter <= myWidgetCollection.Count - 1; counter++)
{
   MessageBox.Show(myWidgetCollection.Item(counter).Name);
}
```

   You can also use **For Each...Next** to cycle through the members of your collection.

10. In Solution Explorer, right-click **WidgetProject** and choose **Properties**. The WidgetProject Property Page opens. Under **Startup Object**, choose **WidgetProject.Form1** from the menu and click **OK** to close the page.

You will now run your test application. You will test the Add method, the Remove method, and the retrieval of Widget objects from the collection.

To test the collection

1. In the Widget Name text box, type **Widget0** and click the Add a Widget button. Repeat this two times, substituting **Widget1** and **Widget2** for **Widget0**.

   Three widgets have now been added to the collection.

2. Click the **Review Widgets** button.

The name of each widget successively appears in a message box.

3. In the Widget Index text box, type **1** and click the **Remove a Widget** button.

   The widget at index 1 is removed. The index is updated dynamically, so that the widget that previously occupied index 2, now occupies index 1.

4. Click the **Review Widgets** button.

   The name of each Widget is again successively displayed in a message box. Note that "Widget1" no longer displays, as it has been removed from the collection.

In this walkthrough, you learned how to implement basic collection functionality by inheriting from the **System.Collections.CollectionBase** class. You learned how to strongly type your collection, and how to implement the **Add** and **Remove** methods and the **Item** property. For more information on the base classes available to you for the creation of collection classes, see System.Collections Namespace.

Exceptions in Components

If you design and run components, they will occasionally cause or encounter errors. When a client program calls a method of your component, any exceptions you throw and/or decide not to handle will be passed along to the client program.

Throwing exceptions to the client is appropriate behavior for components. A well-behaved component does not intrude on the client application's user interface by displaying message boxes containing error text.

Users of an application may be unaware that your component is part of the application they are using. Seeing error messages from a program unknown to them will not help users solve the problem.

The following topics discuss the strategies and mechanics of returning error information to the client application, for the application's developer to deal with as she chooses.

In This Section

Best Practices for Throwing Exceptions from Components
: Describes when to throw exceptions, when not to throw exceptions, what kind of exceptions to throw, and what information to include with the exception.

Throwing Exceptions from Components

Exception Handling Statements
: Provides background on how exceptions are handled in Visual C#.

Best Practices for Throwing Exceptions from Components

When an application calls a method of your component, the method can provide error information by throwing an exception. The client application can implement an exception handler to trap errors that may be thrown by the method.

There are a number of programming tradeoffs to consider when you select an error generation strategy for your component, but the most important consideration should be the convenience of the developer who will use your component. If it is possible for your component to handle an exception internally, it should. The client application should receive exceptions from your component only when additional intervention is required.

When you raise exceptions, the developer who calls your method has the choice of handling the exception or allowing it to be thrown further up the call stack.

Be Consistent

Whatever exceptions you throw from your component should be logically consistent. If you decide to create custom exceptions to report errors unique to your component, they should be limited to reporting that particular error. Do not use a general exception when a more specific one can be used. The purpose of raising an exception is to provide the client application with as much information about how to correct the error and keep the program running smoothly as possible.

If you create and throw custom exceptions in your component, they should be well documented so that developers using your component will best be able to handle them. Your documentation should include a description of the exception, the conditions under which it is likely to occur, suggested ways for resolving the error condition, and any error codes or additional information that the exception returns.

Exceptions Are For Exceptional Circumstances

Do not throw exceptions as a means of communicating between components-use events for that. Exceptions should not be thrown in cases where completely expected results occur. For example, a component that reads text files should not throw an exception when it reaches the end of the file. This is a case where an event would be appropriate. By limiting throwing exceptions to exceptional cases, you will help developers to debug their application rapidly by not having to wade through numerous 'expected' exceptions.

COM-Visible Components and Exceptions

If your component is to be called by a COM client, there are additional considerations to be taken into account. All exceptions thrown from a component to a COM client must provide an error code. With standard exceptions, this code is provided "behind the scenes" via the **HResult** property. If you are creating and throwing custom exceptions, you must set an appropriate **HResult** value. If your custom exception returns an error condition that is similar to a standard error condition, then the **HResult** value for that error condition may be used. Otherwise, you can set the value however you choose. In this case, it is important to document all error codes that might be passed via **HResult** so the developer using your component can implement appropriate responses. For details, see HRESULTs and Exceptions.

Unstructured Error Handling (Visual Basic Only)

Visual Basic .NET also supports unstructured error handling using the **On Error Goto** syntax. While this kind of error handling will continue to function in your components, it is not recommended that it be implemented. Code written using this method of error handling is difficult to debug and maintain, and it can degrade application performance. Structured error handling, using the **Try...Catch...Finally** block, results in code that is easier to maintain, more robust, and more flexible in the way that errors can be handled.

Throwing Exceptions from Components

Any exception that occurs in your component but is not handled will automatically be thrown to the client application. For example, the following will throw an **OverflowException**.

> **C# Note** In order to throw the overflow exception, you must set Check for overflow underflow to true in the Build property page in the Configuration Properties folder of the Project Properties dialog box.

```
' Visual Basic
Dim XX As Integer = 100000
Dim YY As Integer = 100000
Dim ZZ As Integer
' The resulting value is to large to be contained by an integer, thus
' the overflow error is thrown.
ZZ = XX * YY

// C#
int number1 = 100000;
int number2 = 100000;
int product;

// The resulting value is to large to be contained by an integer,
// thus the overflow error is thrown.
product = number1 * number2;
```

If this exception is not handled in the component that generates it, the exception will be bubbled up the call stack until it either finds an appropriate error handler, or the common language runtime default error handler handles it. If you want to pass standard runtime exceptions to the client application, no additional coding is necessary. It will happen automatically.

In areas of code where you suspect an exception might be thrown, you will probably want to provide additional information to the developers using your component.

The following example shows how to catch the exception as it is thrown, and pass it to the client application along with additional information in the message property:

```
' Visual Basic
' The code in the Try block is the code expected to cause an error.
Dim XX As New Integer = 100000
Dim YY As New Integer = 100000
Dim ZZ As Integer
Try
   ' The resulting value is to large to be contained by an integer, thus
   ' the overflow error is thrown.
   ZZ = XX * YY
' If an overflow exception is generated, it will be caught here.
Catch e as OverflowException
   ' Throws a new exception that provides information in the message
   ' string and provides the original exception as the InnerException, e.
   Throw New OverflowException( _
   "The value for the product was larger than an integer could hold", e)
' Catches any other kind of exception that might be generated.
Catch e as Exception
   Throw e
End Try

// C#
// The code in the try block is the code expected to cause an error.
int number1 = 100000;
int number2 = 100000;
int product;
try
{
   product = number1 * number2;
}
// If an overflow exception is generated, it will be caught here.
```

```
catch (OverflowException e)
{
   // Thows a new exception that provides information in the message
   // string and sends on the original exception e.
   throw new OverflowException(
      "The value for the product is larger than an integer can hold.", e);
}
// Catches any other kind of exception that might be generated.
catch (Exception e)
{
   throw e;
}
```

In the preceding example, an exception is thrown when the overflow condition is generated. This exception is caught by the **Catch** block, which then throws a new exception that contains an informative message and the original exception in the **InnerException** property. This new exception is then bubbled up the call stack until it is handled.

To provide additional information when throwing exceptions

1. Determine which parts of your code are likely to throw exceptions, and what exceptions might be thrown.
2. Enclose these areas of code within a **Try...End Try** block.
3. Use the **Catch** statement to catch specific exceptions. For example:

```
' Visual Basic
Catch e as OverflowException
   ' Handling code omitted.
Catch e as NullReferenceException
   ' Handling code omitted.

// C#
catch (OverflowException e)
{
   // Handling code omitted.
}
catch (NullReferenceException e)
{
   // Handling code omitted.
}
```

4. Within the **Catch** block, **Throw** a new exception that provides information in the message property and wraps the original exception in the **InnerException** property. An example is shown:

```
' Visual Basic
Catch e as OverflowException
   Throw New OverflowException( _
      "An overflow occurred in the Widget component.", e)

// C#
catch (OverflowException e)
{
   throw new OverflowException(
      "An overflow occurred in the Widget component.", e);
}
```

Custom Exceptions

If you want to throw a custom exception to the client application, you have that opportunity. You must first create a new exception that inherits from the **Exception** class or a derived class. You must then determine the conditions under which this exception will be thrown, and write the appropriate code to throw the exception.

To create and throw a custom exception

1. Create a custom exception class. This class should inherit **System.Exception** or a class derived from **System.Exception**. An example is shown below.

```
' Visual Basic
Public Class SpeedOfLightException
   Inherits System.Exception
   ' Creates a constructor for the exception that allows you to set the
   ' message property when thrown.
   Public Sub New(ByVal Message As String)
      MyBase.New(Message)
   End Sub
End Class

// C#
public class SpeedOfLightException:System.Exception
{
   //Creates a constructor for the exception that allows you to set the
   // message property when thrown.
   public void SpeedOfLightException(string Message):base(Message)
   {
   }
}
```

2. Decide how you intend to use your exception, and when you want to throw it. You should examine your code and determine those parts where error situations are possible, but a standard exception will not be thrown.
3. When you have determined how your custom exception is to be used, test for error conditions and throw your exception when appropriate. For example:

```
' Visual Basic
Public Sub Accelerate(ByVal finalVelocity as Integer)
   If finalVelocity > cnstSpeedOfLight then
      Throw New SpeedOfLightException("You cannot exceed light speed!")
   End If
   ' (Additional code omitted)
End Sub

// C#
public void Accelerate(int finalVelocity)
{
   if (finalVelocity > cnstSpeedOfLight)
   {
     throw new
        SpeedOfLightException("You cannot exceed light speed!");
   }
   // Additional code omitted.
}
```

   The preceding code receives a value as an argument. It then checks to see if this argument is greater than a constant, and if so throws a SpeedOfLightException. This exception is bubbled up to the calling method, which will then decide how to deal with it.

4. If your component will be exposed to COM, you must determine and set an appropriate **Hresult** value for your exception. For details, see Exception.HResult Property.

Best Practices for Throwing Exceptions from Components

Recommendations on Handling Exceptions in Components

When authoring a component, you should be prepared to handle different kinds of exceptions.

- Exceptions you throw from your component class or its constituent objects, which you handle internally.
- Exceptions you throw from your component class or its constituent objects, which you want to pass along to the client to indicate an error condition in your component.
- Exceptions thrown by a component you are using, but did not write yourself. You may handle these exceptions internally, pass them through to the client, or catch them and then throw an exception of your own.

Handling Errors Internally

Handling the first of these three exception types is no different for a component than for any other application developed using Visual Basic or Visual C#.

Throwing Exceptions to the Caller

Frequently your properties and methods will include code to handle internal errors. Such code may from time to time contain cases in which no sensible internal response is possible. In such cases, it's reasonable for the property or method to fail and return an error to the client. In cases where your component cannot handle the exception that has occurred, you might want to provide additional information about the exception to aid the developer in debugging his code. You might even want to throw a custom exception that provides the developer with very detailed information. These situations are discussed in Throwing Exceptions from Components.

Handling Exceptions from Another Component

If your component calls methods of another component, you must handle exceptions that component may throw. You should be able to obtain a list of these exceptions from the second component's documentation.

It's important to handle such exceptions within your component, and not return them to your caller. The caller was written to use your component, and to handle your component's exceptions. The user or programmer who writes it may have no knowledge of the constituent components you are using.

Encapsulation

The idea that a client application should receive exceptions only from the components it calls directly reflects the object-oriented concept of *encapsulation*. Although your component may use other components, the client application is ignorant of those objects.

In most cases, the best course of action will be for your component to handle any exceptions it receives itself, without breaking or notifying the client application that an exception has occurred. A well-written component will take into account exceptions that may be thrown by secondary components it uses.

In some cases, it may make sense to report the exception to the client application. Cases where additional input from the client is needed will require intervention by the client and cannot be handled by your component alone. In these cases, you should not allow the original exception to bubble up to the client application. Rather, you have two choices:

- Catch the exception thrown in your secondary component and throw a new exception of the same type to the client application.
- Catch the exception thrown in your secondary component and throw a new exception of a custom type, specifically tailored to your situation.

In the first case, you can throw a new exception that originates from your component. You can add a message string to provide the developer with additional information, and you can package all the original exception information in the InnerException property of the new exception. This generates an exception that originates from your component and keeps the client application unaware of any secondary components in use, but contains all of the original information if needed. An example is shown below:

```
' Visual Basic
Try
   ' Calls a method in a secondary component. This call is enclosed in a
   ' Try block in case an exception is thrown by SecondaryComponent.
   SecondaryComponent.CallMethod()
Catch e as OverflowException
```

```
    ' An overflow exception is caught and a new overflow exception is
    ' thrown to the client application. This new excpetion includes the
    ' original exception as the InnerException, and provides an informative
    ' message.
    Throw New OverflowException("An overflow occurred in the xyz method", _
       e)
End Try

// C#
try
{
   // Calls a method in a secondary component. This call is
   // enclosed in a try block in case an exception is thrown
   // by the secondary component.
  secondaryComponent.CallMethod();
}
catch (OverflowException e)
{
   // An overflow exception is caught and a new overflow exception
   // is thrown to the client application. This new exception
   // includes the original exception as the InnerException, and
   // provides an informative message.
   throw new OverflowException("An overflow occurred in the xy method.", _
      e);
}
```

If you need to provide more detailed information to the client application, you might want to create a custom exception. This allows you to pass the original exception to the client application as the **InnerException**, but also allows you to provide information in the form of additional properties specific to your case. Creating and throwing of custom exceptions is discussed in Throwing Exceptions from Components. If you do decide to throw custom exceptions from your component to the client application, it is important to remember to thoroughly document any exceptions your component might throw, so that future developers will be able to respond appropriately to them.

Throwing Exceptions from Components | Handling Exceptions in Your Component

Handling Exceptions in Your Component

If your component uses additional components, it will likely receive exceptions from them from time to time. Good coding practice dictates that you anticipate potential problems and write error-handling code to deal with predicted situations. The .NET Framework provides structured error handling with the **Try...Catch...Finally** statements. Using this method of error handling, it is possible to catch multiple exceptions and provide different error handling for each using multiple **Catch** statements. The **Finally** statement allows you to specify code that will be executed before the error-handling block is exited.

Occasionally, it will be necessary to return an exception from a secondary component to the client application, either by wrapping it in a new exception, or by throwing a custom exception. Recommendations for these practices are discussed in Recommendations on Handling Exceptions in Components.

When writing exception-handling code for your component, try to anticipate what exceptions might occur and write appropriate code to deal with them. In the event that an exception cannot be handled, you should determine what code must be executed before passing on the exception (such as closing a file, saving changes, and so on) and write the appropriate code to the **Finally** block.

To handle exceptions in your component

1. Enclose calls to secondary components within the context of a **Try** block.
2. Determine what exceptions are likely to be thrown by this call, and devise protocols for dealing with them.
3. Enclose these protocols within separate **Catch** blocks.
4. Create an additional **Catch** block to handle any unanticipated exceptions, and pass them on to the client application.
5. Determine what code must be run, even in the event of an exception, and enclose that in a **Finally** block. This code will execute whether an exception is thrown or not.

The following example shows how to create a simple exception handler:

```
' Visual Basic
Public Sub ExceptionDemo
   Try
      ' Calls a method in a secondary component.
      SecondaryComponent.MyMethod()
   Catch e as ArgumentOutOfRangeException
      ' Insert code to fix this specific exception instance.
   Catch e as UnauthorizedAccessException
      ' Insert code to fix this specific exception instance.
   ' This block will catch any other exceptions that are thrown and
   ' package them inside a new exception which will be thrown to the
   ' client application.
   Catch e as Exception
      Throw New Exception("An unhandled exception occured", e)
   ' The Finally block specifies code that will be executed in the event
   ' of an exception.
   Finally
      ' Insert code to save data, release references, and so on.
   End Try
End Sub

// C#
public void ExceptionDemo(int a)
{
   // C#
   try
   {
      secondaryComponent.MyMethod();
   }
   catch (ArgumentOutOfRangeException e)
   {
      // Code to fix this specific exception.
   }
   catch (UnauthorizedAccessException e)
   {
      // Code to fix this specific exception.
   }
```

```
    // This block will catch any other exceptions that are thrown
    // and package them inside a new exception which will be thrown
    // to the client application.
    catch (Exception e)
    {
       throw new Exception("An unhandled exception occurred.", e);
    }
    // The finally block specifies code that will be executed in the
    // event of an exception
    finally
    {
       // Insert code to save data, release references, and so on.
    }
 }
```

Code Security in Components

Code security is a topic of great importance and concern. Keeping your code secure from unauthorized or malicious use while simultaneously allowing authorized users to use your components should be of the highest priority to you the component developer. The following topics provide information on how to write safe and secure components while allowing authorized users to experience your components to the fullest.

In This Section

Adding Security Attributes to Components
Demonstrates how to add security attributes to your components.
Adding Imperative Security Checks to Components
Describes how to use imperative security checks to protect sensitive lines of code from unauthorized use.
Code Security and Signing in Components
Provides conceptual information on code security and decribes the .NET Framework approach to securing your components.

Component Authoring
Provides a high-level overview of component authoring.
Key Security Concepts
Discusses security in the .NET Framework.

Adding Security Attributes to Components

Permissions are the way that your component interacts with the .NET Framework security policy. Permissions can allow your component to perform a variety of potentially unsafe actions that might otherwise be prohibited by the security policy. You can request permissions for your assembly through the use of security attributes. Security attributes modify code members, such as methods or classes. At compile time, security attributes are emitted into metadata that is then stored in the assembly manifest. The assembly manifest is then examined by the common language runtime, and the requested permissions are examined and applied against the local computer security policy. If policy allows, the requested permissions are granted and the assembly is allowed to run.

Security requests are made through the **SecurityAction** parameter of the attribute. The following example shows how:

```
' Visual Basic
Imports System.Security.Permissions
<Assembly: FileIOPermission(SecurityAction.RequestMinimum)>

// C#
using System.Security.Permissions;
[assembly: FileIOPermission(SecurityAction.RequestMinimum)]
```

You can specify different types of permission requests using the **SecurityAction** parameter.

> **Note** Regardless of where the attribute is attached in code, it is effective for the entire assembly. Either the permission will be granted to the whole assembly or to none of it.

You can only be granted the security permissions you request. Therefore, if you only request **FileIOPermission**, for example, you will be denied all other permissions. This is true even if you would have ordinarily been granted other permissions by the default setting of the local security policy.

Security attributes can also be used to protect individual classes or methods. You can use the **SecurityAction** parameter and the **Demand** method to require a particular permission level before allowing access to a class or method. For example, suppose you have a class that deletes files when no longer needed. Uncontrolled access to the class would leave you vulnerable to attacks by malicious users. By demanding permission to use the class, you ensure that all users will have the appropriate level of permission to use potentially dangerous code. The effect is similar to making an imperative security check, but the entire code member is protected, not just the blocks of code. For details on imperative security checks, see
Adding Imperative Security Checks to Components.

To add a permission request to your component

1. Determine the type and level of permission you are requesting.
2. Attach the security attribute to the declaration of your component. Use the appropriate SecurityAction Enumeration to request the desired level of permission.

SecurityAction	Permission level
RequestMinimum	The requested permission is required for the assembly to run, and if not granted, the assembly will not be started
RequestOptional	The assembly will still be run if the requested permission is not granted
RequestRefuse	The assembly will be denied this permission

The following example shows how to attach the **RequestMinimum** permission level:

```
' Visual Basic
Imports System.Security.Permissions
' Indicates that FileIOPermission is required to run this assembly.
<Assembly: FileIOPermission(SecurityAction.RequestMinimum)>
   Public Class FileManager
' Insert code to add and delete files.
End Class

// C#
using System.Security.Permissions;
```

```
// Indicates that FileIOPermission is required to run this assembly.
[assembly: FileIOPermission(SecurityAction.RequestMinimum)]
public class FileManager
{
// Insert code to add and delete files.
}
```

To add a security attribute to a code member of your component

1. Identify the code member you want to protect and the permission that you will require to access it.
2. Attach the security attribute, by calling the **SecurityAction.Demand** method to require the desired permission.

```
' Visual Basic
Imports System.Security.Permissions
<FileIOPermission(SecurityAction.Demand)> Public Sub FileDeleter()
' Insert code to delete files.
End Sub

// C#
using System.Security.Permissions;
[FileIOPermission(SecurityAction.Demand)]
public void FileDeleter()
{
// Insert code to delete files.
}
```

Adding Imperative Security Checks to Components | Code Security and Signing in Components | Security Tutorial | Key Security Concepts

Adding Imperative Security Checks to Components

Imperative security checks allow you to protect specific blocks of code by requiring appropriate permissions. You can use permission objects to add imperative security checks to your code. A permission object is an instance of a specialized class that represents a particular type of permission. For example, the **FileIOPermission** class represents the right to read, append, or write files or directories. You add an imperative security check by creating an instance of the appropriate security object, and then calling that object's **Demand** function. This has the effect of denying access to all callers except those that have the appropriate permission. If a caller does not have the appropriate permissions to execute a called block of code, a **SecurityException** is thrown. For this reason, you should always consider how you want to handle a potential security exception. For details, see Handling Exceptions in Your Component.

To add an imperative security check to your component

1. Determine the kind of security permission that is needed to protect your code. For example, if your code involves using the file system, you would choose **FileIOPermission**. For details on types of code-access permissions, see Code Access Permissions.
2. Decide how you will handle a **SecurityException** if thrown. If you choose to handle it in your component, you should enclose your protected code within a **Try...Catch...Finally** block (**try...catch...finally** in C#), with appropriate code to handle the exception in the **Catch** block. For details, see Handling Exceptions in Your Component.
3. Create an instance of the appropriate permission object immediately preceding the code you want to protect.

   Note Your permission object might require parameters when instanced. For details about which parameters are required, see the .NET Framework reference topic for the specific class.

```
' Visual Basic
Dim MyPermission as New _
   Security.Permissions.FileIOPermission(PermissionState.Unrestricted)

// C#
System.Security.Permissions.FileIOPermission MyPermission = new
System.Security.Permissions.FileIOPermission(
PermissionState.Unrestricted);
```

4. Call the **Demand** method of your permission object. This will require any calling methods to demonstrate the appropriate permissions in order to execute the protected code. This will throw an exception if permission is not granted, so you may want to enclose this statement within structured exception handling.

```
' Visual Basic
Try
   MyPermission.Demand()
Catch e as Exception
   ' Insert code to handle the exception.
End Try

// C#
try
   {
   MyPermission.Demand();
   }
catch (Exception e)
   {
   // Insert code to handle the exception.
   }
```

Code Security and Signing in Components

As a component author, you have three primary concerns when considering security for your components:

- To ensure that your code will run wherever it is deployed.
- To protect your component against unauthorized or malicious use, and in addition, provide safeguards that prevent the exploitation of any bugs in your code.
- To assure the developers and users of your component that your component is authentic, originated from you, and can be trusted.

The .NET Framework security model provides you with the ability to ensure all of these requirements and to provide trustworthy, secure code to your clients.

The common language runtime allows the administrator of a computer to set default permissions for that computer. Simply, the administrator decides what unsafe operations can and cannot be allowed to proceed. On a high-security computer, this may mean that operations required by your component are not allowed to execute. In that case, your component will fail to work properly.

You can address this concern by requesting permissions. Permissions represent potentially unsafe actions, such as access to the file system or calling native code. You request permissions by adding security attributes to your component. At compile time, these attributes are emitted into metadata in the assembly manifest. When the assembly is loaded, the runtime examines the permission requests and applies the security policy. If the policy allows the permissions to be granted, they will be granted. If policy does not allow the requested permissions to be granted, the administrator has the option of revising the policy to allow your component to run. Requesting the permissions required for your component to function ensures that every computer hosting your component will be fully informed as to the permissions required by the code. For details on requesting permissions for your assembly, see Requesting Permissions. For details about how to add security attributes to your code, see Adding Security Attributes to Components.

You can protect your component from unauthorized or malicious use by insuring that callers to your component have the appropriate permissions to use your component. This can be done through *imperative security checks*, which cause permissions to be checked at run time. Using imperative security checks, you are able to create permission objects that safeguard potentially misused regions of code. By calling the **Demand** method of a permission object, you are able to verify that all callers to your protected code member have the appropriate permission to access it. If a caller attempts to access a protected code member without permission, a **SecurityException** is thrown. For details about how to add imperative security checks, see Adding Imperative Security Checks to Components. You can also protect code members using security attributes. For details on protecting your code members with security attributes, see Adding Security Attributes to Components.

Code Signing

When you distribute your component, you will want to be able to assure users that you are the author, that the code is safe and can be trusted, and that the identity of the assembly can be verified. You accomplish this by *signing* your code. You can sign an assembly in two ways:

- Assign your assembly a *strong name*. A strong name consists of the assembly's identity, plus a public key and a digital signature. A strong name is guaranteed to be a unique name, and thereby ensures the identity of your assembly. For details, see Strong-Named Assemblies.

  Although providing a strong name for your assembly guarantees its identity, it is by no means a guarantee that the code can be trusted. Put another way, the strong name uniquely identifies and guarantees the identity of the assembly, but does not guarantee that you wrote it. Nevertheless, a trust decision can reasonably be made based on strong-name identity alone, provided that the assembly is a well-known assembly.

- Use a digital certificate, also called *signcode*. To sign your assembly using signcode, you must go to a third-party authority and prove your identity, whereupon you will obtain a digital certificate that guarantees you as the originator of the component. For details about strong names and signcode, see Assembly Security Considerations.

Special Considerations for Custom Controls

It is important to realize that user code that is executed by the designer at design time will always run fully trusted, even if the project with the user code is located where it would receive less than full-trust at runtime. For example, say you create a Custom Control that makes API calls every second, and locate the code on a network share. Another developer on the network might incorporate your custom control into his project. At design time, the code in the Custom Control will run as fully trusted, and will require no additional permissions. There are two important consequences of this: First is the fact that you might expose your local

machine to a security risk through the network by importing unsecure code. This would only be a concern in the case of a malicious user creating a damaging custom control, followed by a developer mistakenly adding it to his project. A second concern is that applications created by this process may fail to work in a real world environment as a developer may be unaware of what additional permissions may need to be granted.

Code security is a complex and important topic. You are encouraged to make a thorough study of it, so that you might better protect yourself and your clients. For details on how the .NET Framework handles security, see Key Security Concepts.

User Assistance for Components

As a component author, you should provide assistance and documentation for your users about your components. You can provide assistance at design time through descriptive metadata, and at run time by calling HTML Help.

You can supply descriptive information about your component through the use of *attributes*. Attributes are specialized classes that are attached to other classes or class members and are emitted into metadata at compile time. Attributes can provide information to the user or directly to the development environment. For example, the **DescriptionAttribute** attribute, when attached to a property or event, displays a brief descriptive string in the Properties window. Other attributes affect the way the development environment behaves with the component. For example, the **BrowsableAttribute** attribute determines whether a property appears in the Properties window.

Run-time assistance is not usually supplied by a component, but there are some cases where it may make sense. For example, a very large and complex component may have built-in Help so the developers do not have to write extensive documentation. The .NET Framework **Help** object encapsulates the HTML Help 1.*x* engine, and can be used to supply Help to your users at run time with HTML or .chm files. For details, see Specifying a Help File for Your Component.

Attributes Overview
: Provides an overview of attributes and how they are used in the .NET Framework.

Specifying a Help File for Your Component

In most situations, you should let the developers who are using your component enable the run-time Help. In some cases, however, it will make sense to allow your component to display HTML Help when called. HTML Help can be provided for components through the **System.Windows.Forms.Help** object. This object is a static class that encapsulates the HTML Help 1.*x* engine. This class cannot be instantiated, and its methods must be called directly. To display Help, invoke the Help.ShowHelp Method method. This overloaded method requires at least two arguments: the control that acts as the parent control of the Help dialog box, and the URL of the Help file. The Help file can be a compiled HTML Help 1.*x* file (.chm file) or an HTML file in the HTML Help format.

If you are going to incorporate support for a Help file directly in your component, you have two options for when and how to show it:

- The preferred option is to implement a Help method that can be called by the client application. The client application can pass parameters to the Help method to ensure that the correct topics are displayed, and the developer coding with your component has the option of bypassing Help altogether.
- The other option is to invoke the **Help.ShowHelp** method in response to conditions as they occur in code. This approach provides you the most control over what Help is displayed when, but it severely limits future developers in the use of your component.

To specify and display a Help file for your component

1. Create and compile your .chm Help file.
2. If you do not already have a reference to the **System.Windows.Forms** namespace in your component, add one.
3. Create a public method to show Help. This method should provide an easy way for developers to specify what Help they need to display.

```
' Visual Basic
' This method takes parameters from the client application that allow
' the developer to specify when Help is displayed.
Public Sub DisplayHelp (ByVal parent as System.Windows.Forms.Control, _
                        ByVal topic as MyHelpEnum)
   ' The file to display is chosen by the value of the topic
   ' parameter.
   Select Case topic
      Case MyHelpEnum.enumWidgets
         Windows.Forms.Help.ShowHelp(parent, "C:\Help\Widgets.chm")
      Case MyHelpEnum.enumMechanisms
         ' Insert code to implement additional functionality.
   End Select
End Sub

// C#
// This method takes parameters from the client application that allow
// the developer to specify when Help is to be shown.
public void MyHelp(System.Windows.Forms.Control parent,
myHelpEnum topic)
{
   // The file to display is chosen by the value of the topic.
   switch (topic)
   {
      case myHelpEnum.enumWidgets:
         System.Windows.Forms.Help.ShowHelp(parent, " C:\\help\\widgets.chm ");
         break;
      case myHelpEnum.enumMechanism:
         // Insert code to implement additional functionality.
         break;
   }
}
```

Providing Metadata Descriptions About Your Component

You can provide descriptive metadata about your component through *attributes*. Attributes are specialized classes that are applied to code elements. At compile time, attributes are emitted into metadata that is available to the common language runtime or to custom tools and applications through the **System.Reflection** namespace.

Attributes are attached to a component by preceding the component with a reference to the attribute and providing any relevant parameters or flags. This call to the constructor is placed within angle brackets <> in Visual Basic and regular brackets [] in C#.

By convention, all attribute classes end in "Attribute." For example, there are **DescriptionAttribute**, **ObsoleteAttribute**, and **BrowsableAttribute** classes. However, several languages that target the common language runtime, including Visual Basic and C#, do not require the full name of the attribute. For example, the **ObsoleteAttribute** may be referred to in code as **Obsolete**.

To attach an existing attribute to your component

1. Determine which attributes are required for your component.
2. Attach the attributes to your component. Note that you must either use the fully qualified name of the attribute or add the appropriate **Imports** (**using**) statement. The following example shows how to attach the **Description** attribute:

```
' Visual Basic
Imports System.ComponentModel
<Description("This is a description string")> Public Class TheClass
End Class

// C#
using System.ComponentModel
[Description("This is a description string")]
public class TheClass
{
}
```

Custom Attributes

You can also create your own attributes for use with your own custom tools or applications by inheriting from **System.Attribute**. You can add to this base class any custom properties or methods needed by your application.

To create and apply a custom attribute

1. Create a class that inherits from **System.Attribute**.

```
' Visual Basic
Public Class WidgetAttribute
   Inherits System.Attribute
End Class

// C#
public class WidgetAttribute: System.Attribute
{
}
```

2. Determine which properties and methods your attribute needs and write the code for them. The following example shows how to create a WidgetType property that is set in the constructor of the WidgetAttribute class. The **AttributeUsage** attribute sets what code members the attribute can target.

```
' Visual Basic
<AttributeUsage(System.AttributeTargets.Class)> Public Class _
   WidgetAttribute
   Inherits System.Attribute
   Private mWidgetType as WidgetTypeEnum
   ' Creates a readonly property for the WidgetAttribute class.
   Public ReadOnly Property WidgetType as WidgetTypeEnum
```

```
      Get
         Return mWidgetType
      End Get
   End Property
   ' Creates a constructor that accepts a parameter and assigns the
   ' value of that parameter to the WidgetType property.
   Public Sub New(type as WidgetTypeEnum)
      MyBase.New()
      mWidgetType = type
   End Sub
End Class

//C#
public class WidgetAttribute: System.Attribute
{
   private WidgetTypeEnum widgetType;

   // Creates a readonly property for the WidgetAttribute class.
   public WidgetTypeEnum WidgetType
      {
         get {return widgetType;}
      }

   public WidgetAttribute(WidgetTypeEnum type): base()
      {
         widgetType = type;
      }
}
```

3. Apply this attribute as you would any other attribute, being certain to apply any needed parameters.

```
' Visual Basic
<WidgetAttribute(WidgetTypeEnum.VerticalWidget)> _
   Public Class WidgetFortyFive
End Class

// C#
[WidgetAttribute(WidgetTypeEnum.VerticalWidget)]
public class WidgetFortyFive
{
}
```

Providing Metadata for Component Properties, Methods, and Events

You can attach descriptive metadata to your properties, methods, and events by using attributes. Attributes are specialized classes that modify code elements and are emitted into metadata about those code elements at compile time. Design-time attributes interact with the development environment to provide the developer with information about your component. An example of a commonly used attribute is the **DescriptionAttribute**. When attached to a property or event, the **Description** attribute causes a short string to be displayed in the Properties window. An example is shown below:

```
' Visual Basic
<Description("This property specifies the active Widget")> Public _
   Property ActiveWidget as Widget
' Insert code to implementat functionality.
End Property

// C#
[Description("This property specifies the active Widget")]
public Widget ActiveWidget
{
   // Insert code to implementat functionality.
}
```

For details about attributes you can use to enhance design-time support for your component, see Design-Time Attributes for Components.

To attach an attribute to a property, method, or event

- Add a call to the attribute's constructor to the code element you wish to modify. The call is added by placing it in angle brackets <> (for Visual Basic) or brackets [] (for C#), preceding the code element you want to modify.

```
' Visual Basic
<Browsable(False)> Public Property ServingSize as Integer

// C#
[Browsable(false)]
public int ServingSize
```

Control Authoring for Windows Forms

For control authors, the .NET Framework provides an unprecedented wealth of control authoring technology. Authors are no longer limited to designing user controls that act as a collection of preexisting controls. Now, through inheritance, authors can inherit from preexisting user controls, preexisting Windows Forms controls, or even design their own controls that execute custom painting. The new options available give an unprecedented level of flexibility to the design and functionality of the visual interface. To take advantage of these new features, you should be familiar with object-based programming concepts.

> **Visual Basic Note** It is not necessary to have a thorough understanding of inheritance, but you may find it useful to refer to Inheritance.

If you want to create custom controls to use on Web Forms, see Developing ASP.NET Server Controls.

What is the Common Language Specification?
Introduces the Common Language Runtime, which is designed to simplify the creation and use of components. An important aspect of this simplification is enhanced interoperability between components written using different programming languages. The Common Language Specification (CLS) makes it possible to create tools and components that work with multiple programming languages.

Walkthrough: Authoring a User Control with Visual Basic .NET

User controls provide a means by which custom graphical interfaces can be created and reused. A user control is essentially a component with a visual representation. As such, it might consist of one or more Windows Forms controls, components, or blocks of code that can extend functionality by validating user input, modifying display properties, or performing other tasks required by the author. User controls can be placed on Windows Forms in the same manner as other controls. In the first part of this walkthrough, you create a simple user control called ctlClock. In the second part of the walkthrough, you extend the functionality of ctlClock through inheritance.

Creating the Project

When you create a new project, you specify its name to set the root namespace, assembly name, and project name, and ensure that the default component will be in the correct namespace.

To create the ctlClockLib control library and the ctlClock control

1. On the **File** menu, point to **New** and then select **Project** to open the **New Project** dialog box.
2. Select the **Windows Control Library** project template from the list of Visual Basic Projects, and type **ctlClockLib** in the **Name** box.

   > **Note** The Windows Control Library template is not available in the Standard Edition of Visual Basic .NET. For more information, see Visual Basic Standard Edition Features.

   The project name, **ctlClockLib**, is also assigned to the root namespace by default. The root namespace is used to qualify the names of components in the assembly. For example, if two assemblies provide components named ctlClock, you can specify your ctlClock component using `ctlClockLib.ctlClock`. In Solution Explorer, right-click **UserControl1** and select **View Code** from the shortcut menu.

3. Locate the **Class** statement, `Public Class UserControl1`, and change **UserControl1** to **ctlClock** to change the name of the component.

   > **Note** Notice the **Inherits** statement immediately below the **Class** statement. By default, a user control inherits from the **UserControl** class provided by the system. The **UserControl** class provides functionality required by all user controls, and implements standard methods and properties.

4. In Solution Explorer, click **UserControl1**, then in the Properties window, change the **FileName** property to **ctlClock.vb**.
5. From the **File** menu, choose **Save All** to save the project.

Adding Windows Controls and Components to your User Control

A visual interface is an essential part of your user control. This visual interface is implemented by the addition of one or more Windows controls to the User Control Designer. In the following demonstration, you will incorporate Windows controls into your user control and write code to implement functionality.

To add a Label and a Timer to your user control

1. In Solution Explorer, right-click **ctlClock.vb,** and then select **View Designer** from the shortcut menu.
2. In the Toolbox, click the **Windows Forms** tab, and then double-click **Label**.

   A label control named **Label1** is added to your control on the **User Control Designer**.

3. In the designer, click **Label1**. In the Properties window, set the following properties.

Property	Change to
Name	lblDisplay
Text	(blank space)
TextAlign	MiddleCenter
Font.Size	14

4. In the Toolbox, click **Windows Forms**, and then double-click **Timer**.

   Because a timer is a component, it has no visual representation at run time. It therefore does not appear with the controls on the **User Control Designer**, but rather in the component tray.

5. In the component tray, click **Timer1** and set the **Interval** property to **1000** and the **Enabled** property to **True**.

The **Interval** property controls the frequency with which the timer component ticks. Each time **Timer1** ticks, it runs the code in the **Timer1_Tick** event. The interval represents the number of milliseconds between ticks.

6. In the component tray, double-click **Timer1** to go to the **Timer1_Tick** event for ctlClock.
7. Modify the code so that it resembles the following code sample. Be sure to change the access modifier from **Private** to **Protected**:

```
Protected Sub Timer1_Tick(ByVal sender As Object, ByVal e As _
   System.EventArgs) Handles Timer1.Tick
   ' Causes the label to display the current time
   lblDisplay.Text = Format(Now, "hh:mm:ss")
End Sub
```

This code will cause the current time to be shown in **lblDisplay**. Because the interval of **Timer1** was set to 1000, this event will fire every thousand milliseconds, thus updating the current time every second.

8. Modify the method to be overridable. For more information, see the next section of this topic, "Inheriting from a User Control".

```
' Visual Basic
Protected Overridable Sub Timer1_Tick(ByVal sender As Object, ByVal _
   e As System.EventArgs) Handles Timer1.Tick
```

9. From the **File** menu, choose **Save ctlClock** to save the project.

Adding Properties to Your User Control

Your clock control now encapsulates a **Label** control and a **Timer** component, each with its own set of inherent properties. While the individual properties of these controls will not be accessible to subsequent users of your control, you can create and expose custom properties by writing the appropriate blocks of code. In the following section, you will add properties to your control that enable the user to change the color of the background and text.

To add a Property to your user control

1. In Solution Explorer, right-click **ctlClock.vb**, and then click **View Code** from the shortcut menu.

   The Code Editor for your control opens.

2. Locate the `Inherits System.Windows.Forms.UserControl` statement. Beneath it, type:

```
Private colFColor as Color
Private colBColor as Color
```

These statements create the private variables that you will use to store the values for the properties you are about to create.

3. Type the following code beneath the variable declarations from step 2:

```
' Declares the name and type of the property.
Property ClockBackColor() as Color
   ' Retrieves the value of the private variable colBColor.
   Get
      Return colBColor
   End Get
   ' Stores the selected value in the private variable colBColor, and
   ' updates the backcolor of the label control lblDisplay.
   Set(ByVal Value as Color)
      colBColor = Value
      lblDisplay.BackColor = ColBColor
   End Set

End Property
' Provides a similar set of instructions for the forecolor.
Property ClockForeColor() as Color
```

```
    Get
       Return colFColor
    End Get
    Set(ByVal Value as Color)
       colFColor = Value
       lblDisplay.ForeColor = ColFColor
    End Set
 End Property
```

The preceding code makes two custom properties, ClockForeColor and ClockBackColor, available to subsequent users of this control by invoking the `Property` statement. The **Get** and **Set** statements provide for storage and retrieval of the property value, as well as code to implement functionality appropriate to the property.

4. From the **File** menu, choose **Save ctlClock.vb** to save the project.

Testing Your Control

Controls are not stand-alone projects; they must be hosted in a container. In order to test your control, you must provide a test project within which it runs. In this section, you will build your control and test it in a Windows Form.

To build your control

- On the **Build** menu, click **Build ctlClockLib**.

To create a test project

1. On the **File** menu, point to **Add Project** and then click **New Project** to open the **Add New Project** window.
2. Click **Windows Application**, and in the **Name** box, type **Test**, and click **OK**.
3. In Solution Explorer, right-click the **References** node for your test project. Click **Add Reference** to display the **Add Reference** dialog box.
4. Click the tab labeled **Projects**. Your project will be listed under **Project Name**.
5. Double-click your project.

   Note that your project now appears in the **Selected Components** window.

After you have added your reference, you can place your control in your form.

To test your control

1. In the Toolbox, click **My User Controls**, and then scroll down until the control icon representing **ctlClock** is displayed.
2. Double-click the **ctlClock** icon.

   A copy of your control is now added to your form. Note that it displays the current time and is updated each second.

3. In the Toolbox, select the icon and move your mouse over your form.
4. Hold down the left mouse button while moving the mouse across the form.

   Another copy of your control is drawn onto the form. You can add as many copies of your timer to your form as you want.

5. In the designer, click one of the instances of **ctlClock**.

   The properties for this instance are displayed in the Properties window.

6. In the Properties window, locate the **ClockBackColor** property, and then select the property to display the color palette.
7. Choose a color by clicking it.

   The background color of your control changes to the color you selected.

8. Use a similar sequence of events to verify that the **ClockForeColor** property is functioning as expected.

In this section, you have seen how components and Windows controls can be combined with code and packaging to provide custom functionality in the form of a user control. You have learned to expose properties in your user control, and how to test your control after it is complete. In the next section you will learn how to construct an inherited user control using **ctlClock** as a base.

Inheriting from a User Control

In the previous section, you learned how to combine Windows controls, components, and code into reusable user controls. Your user control can now be used as a base upon which other controls can be built. The process of deriving a class from a base class is called *inheritance*. In this section, you will create a user control called ctlAlarmClock. This control will be derived from its parent control, ctlClock. You will learn to extend the functionality of ctlClock by overriding parent methods and adding new methods and properties.

Creating the Inherited Control

The first step in creating an inherited control is to derive it from its parent. This action creates a new control that has all of the properties, methods, and graphical characteristics of the parent control, but can also act as a base for the addition of new or modified functionality.

To create the inherited control

1. In Solution Explorer, click **ctlClockLib**.
2. From the **Project** menu, select **Add Inherited Control**.

   The **Add New Item** window opens with **Inherited User Control** selected.

3. In the **Name** box, type **ctlAlarmClock.vb**, and click **Open**.

   The **Inheritance Picker** window appears.

4. Under **Component Name**, double-click **ctlClock**.
5. In Solution Explorer, browse the current projects. Note that a file called **ctlAlarmClock** has been added.

Adding the Alarm Properties

Properties are added to an inherited control in the same way they are added to a user control. You will now use the property declaration syntax to add two properties to your control: **AlarmTime**, which will store the value of the date and time the alarm is to go off, and **AlarmSet**, which will indicate whether or not the alarm is set.

To add Properties to your user control

1. In Solution Explorer, right-click **ctlAlarmClock** and select **View Code** from the shortcut menu.
2. Locate the `Inherits` statement. Note that your control inherits from **ctlClockLib.ctlClock**. Beneath the `Inherits` statement, type the following code:

```
Private dteAlarmTime As Date
Private blnAlarmSet As Boolean
' These properties will be declared as public to allow future
' developers to access them.
Public Property AlarmTime() As Date
   Get
      Return dteAlarmTime
   End Get
   Set(ByVal Value as Date)
      dteAlarmTime = Value
   End Set
End Property
Public Property AlarmSet() As Boolean
   Get
      Return blnAlarmSet
   End Get
   Set(ByVal Value as Boolean)
      blnAlarmSet = Value
   End Set
End Property
```

Adding to the Graphical Interface of Your Control

Your inherited control has a visual interface that is identical to the control it inherits from. It possesses the same constituent controls as its parent control, but the properties of the constituent controls will not be available unless they were specifically

exposed. You may add to the graphical interface of an inherited user control in the same manner as you would add to any user control. To continue adding to your alarm clock's visual interface, you will add a label control that will flash when the alarm is sounding.

To add the label control

1. In Solution Explorer, right-click **ctlAlarmClock** and select **View Designer** from the shortcut menu.

   The designer for **ctlAlarmClock** opens in the main window.

2. Click the display portion of the control, and observe the Properties window.

   Note that while all the properties are displayed, they are dimmed. This indicates that these properties are native to **lblDisplay**, and cannot be modified or accessed in the properties window. By default, controls contained in a user control are `Private`, and their properties are not accessible by any means.

   > **Tip** If you want subsequent users of your user control to have access to its internal controls, declare them as Public or Protected. This will allow you to set and modify properties of controls contained within your user control by using the appropriate code.

3. Add a **Label** control to your user control.
4. Using the mouse, move the label control immediately beneath the display box. In the Properties window, set the following properties:

Property	Setting
Name	**lblAlarm**
Text	**Alarm Is Sounding!**
TextAlign	**Middle Center**
Visible	**false**

Adding the Alarm Functionality

In the previous sections, you added properties and a control that will enable alarm functionality in your user control. In this section, you will add code to compare the current time to the alarm time, and if they are the same, to sound and flash an alarm. By overriding the **Timer1_Tick** method of **ctlClock**, and adding additional code to it, you will extend the capability of **ctlAlarmClock** while retaining all of the inherent functionality of **ctlClock**.

To override the Timer1_Tick method of ctlClock

1. In the Code Editor, locate the `Private blnAlarmSet As Boolean` statement. Immediately beneath it, add the following statement:

```
Dim blnColorTicker as Boolean
```

2. In the Code Editor, locate the `End Class` statement. It can be found at the bottom of the page.
3. Just before the `End Class` statement, add the following code:

```
Protected Overrides Sub Timer1_Tick(ByVal sender As Object, ByVal e _
   As System.EventArgs)
   ' Calls the Timer1_Tick method of ctlClock.
   MyBase.Timer1_Tick(sender, e)
   ' Checks to see if the Alarm is set.
   If AlarmSet = False Then
      Exit Sub
   End If
   ' If the date, hour and minute of the alarm time are the same as
   ' now, flash and Beep!
   If AlarmTime.Date = Now.Date And AlarmTime.Hour = Now.Hour And _
      AlarmTime.Minute = Now.Minute Then
      ' Sounds an audible Beep
```

```
        Beep()
        ' Makes lblAlarmVisible, and changes the backcolor based on the
        ' value of blnColorTicker. The backcolor of the label will
        ' flash once per tick of the clock.
        lblAlarm.Visible = True
        If blnColorTicker = False Then
           lblAlarm.BackColor = Color.PeachPuff
           blnColorTicker = True
        Else
           lblAlarm.BackColor = Color.Plum
           blnColorTicker = False
        End If
     Else
        ' Once the alarm has sounded for a minute, the label is made
        ' invisible again.
        lblAlarm.Visible = False
     End If
  End Sub
```

The addition of this code accomplishes several tasks. The `Overrides` statement directs the control to use this method in place of the method that was inherited from the base control. When this method is called, it calls the method it overrides by invoking the `MyBase.Timer1_Tick` statement, ensuring that all of the functionality incorporated in the original control is reproduced in this control. It then runs additional code to incorporate the alarm functionality. A flashing label control will appear when the alarm is sounding, and an audible beep will be heard.

Note that since you are overriding an inherited event handler, you do not have to specify the event with the `Handles` keyword. The event is already hooked up. All you are overriding is the implementation of the handler.

Your alarm clock control is almost complete. The only thing that remains is to implement a way to turn it off. To do this, we will add code to the **lblAlarm_Click** method.

To implement the shutoff method

1. In Solution Explorer, right-click **ctlAlarmClock.vb** and click **View Designer**.

   The designer opens.

2. In the designer, double-click **lblAlarm**. The **Code Editor** opens to the `Protected Sub lblAlarm_Click` line.
3. Modify this method so that it resembles the following:

```
Protected Sub lblAlarm_Click(ByVal sender As Object, ByVal e As _
 System.EventArgs) Handles lblAlarm.Click
   ' Turns off the alarm.
   AlarmSet = False
   ' Hides the flashing label.
   lblAlarm.Visible = False
End Sub
```

4. From the **File** menu, choose **Save ctlAlarmClock.vb** to save the project.

Testing Your Inherited Control

As with a standard user control, an inherited user control cannot stand alone and must be hosted in a form or other container. Since **ctlAlarmClock** has a greater depth of functionality, additional code is required to test it. In this section, you will write a simple program to test the functionality of **ctlAlarmClock**. You will write code to set and display the **AlarmTime** property of **ctlAlarmClock**, and will test its inherent functions.

To build and add your control to a test form

1. In Solution Explorer, click **ctlClockLib**. On the **Build** menu, choose **Build ctlClockLib**.
2. Add a new **Windows Application** project to the solution, and name it **Test2**.
3. In Solution Explorer, right-click the **References** node for your test project. Click **Add Reference** to display the **Add**

Reference window. Click the tab labeled **Projects**. The project **ctlClockLib** will be listed under Project Name. Double-click **ctlClockLib**, and note that it now appears in the Selected Components window.

4. In the Toolbox, click **My User Controls**.
5. Scroll down until the icon for **ctlAlarmClock** comes into view.
6. Double-click **ctlAlarmClock** to add a copy of **ctlAlarmClock** to your form.
7. Locate and double-click **DateTimePicker** to add a **DateTimePicker** control to your form, and add a **Label** control by double-clicking **Label**.
8. Use the mouse to position the controls in a convenient place on the form.
9. Set the properties of these controls as follows:

Control	Property	Value
Label1	**Text**	(leave blank)
	Name	**lblTest**
DateTimePicker1	**Name**	**dtpTest**
	Format	**Time**

10. In the designer, double-click **dtpTest**.

    The Code Editor opens to `Protected Sub dtpTest_ValueChanged`.

11. Modify the code so that it resembles the following:

```
Protected Sub dtpTest_ValueChanged(ByVal sender As Object, ByVal e As _
   System.EventArgs) Handles dtpTest.ValueChanged
   ctlAlarmClock1.AlarmTime = dtpTest.Value
   ctlAlarmClock1.AlarmSet = True
   lblTest.Text = "Alarm Time is " & Format(ctlAlarmClock1.AlarmTime, _
      "hh:mm")
End Sub
```

12. In Solution Explorer, right-click **Test2** and choose **Set as StartUp Project** from the shortcut menu.
13. From the **Debug** menu, choose **Start**.

    The test program starts. Note that the current time is updated in the **ctlAlarmClock** control, and that the starting time is shown in the **DateTimePicker** control.

14. Click the **DateTimePicker** where the minutes of the hour are displayed.
15. Using the keyboard, set a value for minutes that is one minute greater than the current time shown by **ctlAlarmClock**.

    The time for the alarm setting is shown in **lblTest**.

16. Wait for the displayed time to reach the alarm setting time.

    When the displayed time reaches the time to which the alarm is set, the beep will sound and **lblAlarm** will flash. Turn off the alarm by clicking **lblAlarm**. You may now reset the alarm.

This walkthrough has covered a number of key concepts. You have learned to create a user control by combining controls and components into a user control container. You have learned to add properties to your control, and to write code to implement custom functionality. In the second section, you learned to extend the functionality of a given user control through inheritence, and to alter the functionality of host methods by overriding those methods.

See Also

Authoring User Controls | Displaying Your Control in the Customize Toolbox Dialog Box | Component Authoring Walkthroughs

Walkthrough: Authoring a User Control with Visual C#

User controls provide a means by which custom graphical interfaces can be created and reused. A user control is essentially a component with a visual representation. As such, it might consist of one or more Windows Forms controls, components, or blocks of code that can extend functionality by validating user input, modifying display properties, or performing other tasks required by the author. User controls can be placed on Windows Forms in the same manner as other controls. In the first part of this walkthrough, you create a simple user control called ctlClock. In the second part of the walkthrough, you extend the functionality of ctlClock through inheritance.

Creating the Project

When you create a new project, you specify its name to set the root namespace, assembly name, and project name, and ensure that the default component will be in the correct namespace.

To create the ctlClockLib control library and the ctlClock control

1. On the **File** menu, point to **New** and then select **Project** to open the **New Project** dialog box.
2. Select the **Windows Control Library** project template from the list of C# Projects, and type **ctlClockLib** in the **Name** box.

   > **Note** The Windows Control Library template is not available in the Standard Edition of Visual C# .NET. For more information, see Visual C# Standard Edition Features.

   The project name, **ctlClockLib**, is also assigned to the root namespace by default. The root namespace is used to qualify the names of components in the assembly. For example, if two assemblies provide components named ctlClock, you can specify your ctlClock component using `ctlClockLib.ctlClock`. In Solution Explorer, right-click **UserControl1** and select **View Code** from the shortcut menu.

3. Locate the **Class** statement, `public class UserControl1`, and change **UserControl1** to **ctlClock** to change the name of the component.

   > **Note** By default, a user control inherits from the **UserControl** class provided by the system. The **UserControl** class provides functionality required by all user controls, and implements standard methods and properties.

4. Locate the constructor, `public UserControl1()`, and change `UserControl1` to `ctlClock`.
5. In Solution Explorer, click **UserControl1**, then in the Properties window, change the **FileName** property to **ctlClock.cs**.
6. From the **File** menu, choose **Save All** to save the project.

Adding Windows Controls and Components to your User Control

A visual interface is an essential part of your user control. This visual interface is implemented by the addition of one or more Windows controls to the User Control Designer. In the following demonstration, you will incorporate Windows controls into your user control and write code to implement functionality.

To add a Label and a Timer to your user control

1. In Solution Explorer, right-click **ctlClock.cs,** and then select **View Designer**.
2. In the Toolbox, click the **Windows Forms** tab, and then double-click **label**.

   A label control named **label1** is added to your control on the **User Control Designer**.

3. In the designer, click **label1**. In the Properties window, set the following properties.

Property	Change to
Name	lblDisplay
Text	(blank space)
TextAlign	MiddleCenter
Font.Size	14

4. In the Toolbox, click **Windows Forms**, and then double-click **Timer**.

   Because a timer is a component, it has no visual representation at run time. It therefore does not appear with the controls on the **User Control Designer**, but rather in the component tray.

5. In the component tray, click **timer1** and set the **Interval** property to **1000**, and the **Enabled** property to **true**.

The **Interval** property controls the frequency with which the timer component ticks. Each time **timer1** ticks, it runs the code in the **timer1_Tick** event. The interval represents the number of milliseconds between ticks.

6. In the component tray, double-click **timer1** to go to the **timer1_Tick** event for ctlClock.
7. Modify the code so that it resembles the following code sample. Be sure to change the access modifier from **private** to **protected**:

```
protected void timer1_Tick(object sender, System.EventArgs e)
{
   // Causes the label to display the current time
   lblDisplay.Text = DateTime.Now.ToLongTimeString();
}
```

This code will cause the current time to be shown in **lblDisplay**. Because the interval of **timer1** was set to 1000, this event will fire every thousand milliseconds, thus updating the current time every second.

8. Modify the method to be overridable with the **virtual** keyword. For more information, see the next section of this topic, "Inheriting from a User Control".

```
protected virtual void timer1_Tick(object sender, System.EventArgs e)
```

9. From the **File** menu, choose **Save All** to save the project.

Adding Properties to Your User Control

Your clock control now encapsulates a **Label** control and a **Timer** component, each with its own set of inherent properties. While the individual properties of these controls will not be accessible to subsequent users of your control, you can create and expose custom properties by writing the appropriate blocks of code. In the following section, you will add properties to your control that enable the user to change the color of the background and text.

To add a Property to your user control

1. In Solution Explorer, right-click **ctlClock.cs**, and then click **View Code** from the shortcut menu.

   The Code Editor for your control opens.

2. Locate the `public class ctlClock` statement. Beneath the opening `{`, type:

```
private Color colFColor;
private Color colBColor;
```

These statements create the private variables that you will use to store the values for the properties you are about to create.

3. Type the following code beneath the variable declarations from step 2:

```
// Declares the name and type of the property.
public Color ClockBackColor
// Retrieves the value of the private variable colBColor.
{
   get
   {
      return colBColor;
   }
   // Stores the selected value in the private variable colBColor, and
   // updates the backcolor of the label control lblDisplay.
   set
   {
      colBColor = value;
      lblDisplay.BackColor = colBColor;
   }
}
// Provides a similar set of instructions for the forecolor.
public Color ClockForeColor
```

```
{
   get
   {
      return colFColor;
   }
   set
   {
      colFColor = value;
      lblDisplay.ForeColor = colFColor;
   }
}
```

The preceding code makes two custom properties, ClockForeColor and ClockBackColor, available to subsequent users of this control. The **get** and **set** statements provide for storage and retrieval of the property value, as well as code to implement functionality appropriate to the property.

4. From the **File** menu, choose **Save All** to save the project.

Testing Your Control

Controls are not stand-alone applications; they must be hosted in a container. In order to test your control, you must provide a test project within which it runs. In this section, you will build your control and test it in a Windows Form.

To build your control

- On the **Build** menu, click **Build**.

To create a test project

1. On the **File** menu, point to **Add Project** and then click **New Project** to open the **Add New Project** window.
2. Click **Windows Application**, and in the **Name** box, type **Test**.
3. In Solution Explorer, right-click the **References** node for your test project. Click **Add Reference** to display the **Add Reference** dialog box.
4. Click the tab labeled **Projects**. Your user control project will be listed under **Project Name**.
5. Double-click your project.

   Note that your project now appears in the **Selected Components** window.

After you have added your reference, you can place your control in your form.

To test your control

1. In the Toolbox, click **My User Controls**, and then scroll down until the control icon representing **ctlClock** is displayed.
2. Double-click the **ctlClock** icon.

   A copy of your control is now added to your form. Note that it displays the current time and is updated each second.

3. In the **Toolbox**, select the icon and move your mouse over your form.
4. Hold down the left mouse button while moving the mouse across the form.

   Another copy of your control is drawn onto the form. You can add as many copies of your timer to your form as you want.

5. In the designer, click one of the instances of **ctlClock**.

   The properties for this instance are displayed in the Properties window.

6. In the Properties window, locate the **ClockBackColor** property, then select the property to display the color palette.
7. Choose a color by clicking it.

   The background color of your control changes to the color you selected.

8. Use a similar sequence of events to verify that the **ClockForeColor** property is functioning as expected.

In this section, you have seen how components and Windows controls can be combined with code and packaging to provide custom functionality in the form of a user control. You have learned to expose properties in your user control, and how to test your control after it is complete. In the next section you will learn how to construct an inherited user control using **ctlClock** as a

base.

Inheriting from a User Control

In the previous section, you learned how to combine Windows controls, components, and code into reusable user controls. Your user control can now be used as a base upon which other controls can be built. The process of deriving a class from a base class is called *inheritance*. In this section, you will create a user control called ctlAlarmClock. This control will be derived from its parent control, ctlClock. You will learn to extend the functionality of ctlClock by overriding parent methods and adding new methods and properties.

Creating the Inherited Control

The first step in creating an inherited control is to derive it from its parent. This action creates a new control that has all of the properties, methods, and graphical characteristics of the parent control, but can also act as a base for the addition of new or modified functionality.

To create the inherited control

1. In Solution Explorer, click **ctlClockLib**.
2. From the **Project** menu, select **Add Inherited Control**.

   The **Add New Item** window opens with **Inherited User Control** selected.

3. In the **Name** box, type **ctlAlarmClock.cs**, and click **Open**.

   The **Inheritance Picker** window appears.

4. Under **Component Name**, double-click **ctlClock**.
5. In Solution Explorer, browse the current projects. Note that a file called **ctlAlarmClock** has been added.

Adding the Alarm Properties

Properties are added to an inherited control in the same way they are added to a user control. You will now use the property declaration syntax to add two properties to your control: **AlarmTime**, which will store the value of the date and time the alarm is to go off, and **AlarmSet**, which will indicate whether or not the alarm is set.

To add Properties to your user control

1. In Solution Explorer, right-click **ctlAlarmClock** and select **View Code**.
2. Locate the `public class` statement. Note that your control inherits from **ctlClockLib.ctlClock**. Beneath the `{` statement, type the following code:

```
private DateTime dteAlarmTime;
private bool blnAlarmSet;
// These properties will be declared as public to allow future
// developers to access them.
public DateTime AlarmTime
{
   get
   {
      return dteAlarmTime;
   }
   set
   {
      dteAlarmTime = value;
   }
}
public bool AlarmSet
{
   get
   {
      return blnAlarmSet;
   }
   set
```

```
    {
       blnAlarmSet = value;
    }
 }
```

Adding to the Graphical Interface of Your Control

Your inherited control has a visual interface that is identical to the control it inherits from. It possesses the same constituent controls as its parent control, but the properties of the constituent controls will not be available unless they were specifically exposed. You may add to the graphical interface of an inherited user control in the same manner as you would add to any user control. To continue adding to your alarm clock's visual interface, you will add a label control that will flash when the alarm is sounding.

To add the label control

1. In Solution Explorer, right-click **ctlAlarmClock** and select **View Designer** from the shortcut menu.

   The designer for **ctlAlarmClock** opens in the main window.

2. Click the display portion of the control, and observe the Properties window.

   Note that while all the properties are displayed, they are dimmed. This indicates that these properties are native to **lblDisplay**, and cannot be modified or accessed in the properties window. By default, controls contained in a user control are `private`, and their properties are not accessible by any means.

   > **Tip** If you want subsequent users of your user control to have access to its internal controls, declare them as **public** or **protected**. This will allow you to set and modify properties of controls contained within your user control by using the appropriate code.

3. Add a **Label** control to your user control.
4. Using the mouse, move the label control immediately beneath the display box. In the Properties window, set the following properties:

Property	Setting
Name	**lblAlarm**
Text	**Alarm!**
TextAlign	**Middle Center**
Visible	**false**

Adding the Alarm Functionality

In the previous sections, you added properties and a control that will enable alarm functionality in your user control. In this section, you will add code to compare the current time to the alarm time, and if they are the same, to flash an alarm. By overriding the **timer1_Tick** method of **ctlClock**, and adding additional code to it, you will extend the capability of **ctlAlarmClock** while retaining all of the inherent functionality of **ctlClock**.

To override the timer1_Tick method of ctlClock

1. In the Code Editor, locate the `private bool blnAlarmSet;` statement. Immediately beneath it, add the following statement:

```
private bool blnColorTicker;
```

2. In the Code Editor, locate the `}` at the end of the class.
3. Just before the `}`, add the following code:

```
protected override void timer1_Tick(object sender, System.EventArgs e)
{
   // Calls the Timer1_Tick method of ctlClock.
   base.timer1_Tick(sender, e);
   // Checks to see if the Alarm is set.
   if (AlarmSet == false)
      return;
   else
```

```
        // If the date, hour and minute of the alarm time are the same as
        // now, flash!
    {
        if (AlarmTime.Date == DateTime.Now.Date && AlarmTime.Hour ==
           DateTime.Now.Hour && AlarmTime.Minute == DateTime.Now.Minute)
        {
           // Makes lblAlarmVisible, and changes the backcolor based on
           // the value of blnColorTicker. The backcolor of the label
           // will flash once per tick of the clock.
           lblAlarm.Visible = true;
           if (blnColorTicker == false)
           {
              lblAlarm.BackColor = Color.Red;
              blnColorTicker = true;
           }
           else
           {
              lblAlarm.BackColor = Color.Blue;
              blnColorTicker = false;
           }
        }
        else
        {
           // Once the alarm has sounded for a minute, the label is made
           // invisible again.
           lblAlarm.Visible = false;
        }
    }
}
```

The addition of this code accomplishes several tasks. The `override` statement directs the control to use this method in place of the method that was inherited from the base control. When this method is called, it calls the method it overrides by invoking the `base.timer1_Tick` statement, ensuring that all of the functionality incorporated in the original control is reproduced in this control. It then runs additional code to incorporate the alarm functionality. A flashing label control will appear when the alarm is triggered.

Your alarm clock control is almost complete. The only thing that remains is to implement a way to turn it off. To do this, we will add code to the **lblAlarm_Click** method.

To implement the shutoff method

1. In Solution Explorer, right-click **ctlAlarmClock.cs** and click **View Designer**.

   The designer opens.

2. Add a button to the control. Set the properties of the button as follows:

Property	Value
Name	**btnAlarmOff**
Text	**Disable Alarm**

3. In the designer, double-click **btnAlarmOff**.

   The Code Editor opens to the `private void btnAlarmOff_Click` line.

4. Modify this method so that it resembles the following:

```
private void btnAlarmOff_Click(object sender, System.EventArgs e)
{
   // Turns off the alarm
   AlarmSet = false;
   // Hides the flashing label
   lblAlarm.Visible = false;
}
```

5. From the **File** menu, choose **Save All** to save the project.

Testing Your Inherited Control

As with a standard user control, an inherited user control cannot stand alone and must be hosted in a form or other container. Since **ctlAlarmClock** has a greater depth of functionality, additional code is required to test it. In this section, you will write a simple program to test the functionality of **ctlAlarmClock**. You will write code to set and display the **AlarmTime** property of **ctlAlarmClock**, and will test its inherent functions.

To build and add your control to a test form

1. In Solution Explorer, click **ctlClockLib**. On the **Build** menu, choose **Build ctlClockLib**.
2. Add a new **Windows Application** project to the solution, and name it **Test2**.
3. In Solution Explorer, right-click the **References** node for your test project. Click **Add Reference** to display the **Add Reference** window. Click the tab labeled **Projects**. Your project will be listed under **Project Name**. Double-click your project, and note that it now appears in the **Selected Components** window.
4. In the Toolbox, click **My User Controls**.
5. Scroll down until the icon for **ctlAlarmClock** comes into view.
6. Double-click **ctlAlarmClock** to add a copy of **ctlAlarmClock** to your form.
7. In the Toolbox, locate and double-click **DateTimePicker** to add a **DateTimePicker** control to your form, and add a **Label** control by double-clicking **Label**.
8. Use the mouse to position the controls in a convenient place on the form.
9. Set the properties of these controls as follows:

Control	Property	Value
label1	**Text**	(leave blank)
	Name	**lblTest**
dateTimePicker1	**Name**	**dtpTest**
	Format	**Time**

10. In the designer, double-click **dtpTest**.

    The Code Editor opens to `private void dtpTest_ValueChanged`.

11. Modify the code so that it resembles the following:

```
private void dtpTest_ValueChanged(object sender, System.EventArgs e)
{
   ctlAlarmClock1.AlarmTime = dtpTest.Value;
   ctlAlarmClock1.AlarmSet = true;
   lblTest.Text = "Alarm Time is " +
      ctlAlarmClock1.AlarmTime.ToShortTimeString();
}
```

12. In Solution Explorer, right-click **Test2** and choose **Set as StartUp Project** from the shortcut menu.
13. From the **Debug** menu, choose **Start**.

    The test program starts. Note that the current time is updated in the **ctlAlarmClock** control, and that the starting time is shown in the **DateTimePicker** control.

14. Click the **DateTimePicker** where the minutes of the hour are displayed.
15. Using the keyboard, set a value for minutes that is one minute greater than the current time shown by **ctlAlarmClock**.

    The time for the alarm setting is shown in **lblTest**.

16. Wait for the displayed time to reach the alarm setting time.

    When the displayed time reaches the time to which the alarm is set the **lblAlarm** will flash. Turn off the alarm by clicking **btnAlarmOff**. You may now reset the alarm.

This walkthrough has covered a number of key concepts. You have learned to create a user control by combining controls and components into a user control container. You have learned to add properties to your control, and to write code to implement custom functionality. In the second section, you learned to extend the functionality of a given user control through inheritence,

and to alter the functionality of host methods by overriding those methods.

Displaying Your Control in the Customize Toolbox Dialog Box |
Walkthrough: Inheriting From a Windows Forms Control with Visual C#

Walkthrough: Inheriting from a Windows Forms Control with Visual Basic .NET

Visual Basic .NET provides you with the ability to create powerful custom controls through *inheritance*. Through inheritance you are able to create controls that retain all of the inherent functionality of standard Windows Forms controls but also incorporate custom functionality. In this walkthrough, you will create a simple inherited control called ValueButton. This button will inherit functionality from the standard Windows Forms button, and will expose a custom property called ButtonValue.

Creating the Project

When you create a new project, you specify its name in order to set the root namespace, assembly name, and project name, and to ensure that the default component will be in the correct namespace.

To create the ValueButtonLib control library and the ValueButton control

1. On the **File** menu, point to **New** and then click **Project** to open the **New Project** dialog box.
2. Select the **Windows Control Library** project template from the list of Visual Basic projects, and type **ValueButtonLib** in the **Name** box.

   > **Note** The Windows Control Library template is not available in the Standard Edition of Visual Basic .NET or Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

   The project name, ValueButtonLib, is also assigned to the root namespace by default. The root namespace is used to qualify the names of components in the assembly. For example, if two assemblies provide components named ValueButton, you can specify your ValueButton component using `ValueButtonLib.ValueButton`. For more information, see Components and Assemblies.

3. In Solution Explorer, right-click **UserControl1.vb** and select **View Code** from the shortcut menu.
4. Locate the **Class** statement, `Public Class UserControl1`, and change **UserControl1** to **ValueButton** to change the name of the component.
5. Locate the statement `Inherits System.Windows.Forms.UserControl`, and change **System.Windows.Forms.UserControl** to **System.Windows.Forms.Button.** This allows your inherited control to inherit all the functionality of the **Button** control.
6. In Solution Explorer, click **UserControl1.vb** and in the Properties window, change the **FileName** property to **ValueButton.vb**.
7. From the **File** menu, choose **Save All** to save the project.

   Note that the User Control Designer is no longer available. Because the **Button** control does its own painting, you are unable to modify its appearance in the designer. Its visual representation will be exactly the same as that of the class it inherits from (that is, **Button**) unless modified in the code.

Adding a Property to Your Inherited Control

One possible use of inherited Windows Forms controls is the creation of controls that are identical in look and feel of standard Windows Forms controls, but expose custom properties. In this section, you will add a property called ButtonValue to your control.

To add the Value property

1. In Solution Explorer, right-click **ValueButton.vb**, and then click **View Code** from the shortcut menu.
2. Locate the `Inherits System.Windows.Forms.Button` statement. Immediately beneath this statement, type the following code:

```
' Creates the private variable that will store the value of your
' property.
Private varValue as integer
' Declares the property.
Property ButtonValue() as Integer
' Sets the method for retrieving the value of your property.
   Get
      Return varValue
```

```
    End Get
  ' Sets the method for setting the value of your property.
    Set(ByVal Value as Integer)
       varValue = Value
    End Set
  End Property
```

This code sets the methods by which the ButtonValue property is stored and retrieved. The **Get** statement sets the value returned to the value that is stored in the private variable **varValue**, and the **Set** statement sets the value of the private variable by use of the **Value** keyword.

3. From the **File** menu, choose **Save All** to save the project.

Testing Your Control

Controls are not stand-alone projects; they must be hosted in a container. In order to test your control, you must provide a test project for it to run in. You must also make your control accessible to the test project by building (compiling) it. In this section, you will build your control and test it in a Windows Form.

To build your control

- On the **Build** menu, click **Build**.

  The build should be successful with no compiler errors or warnings.

To create a test project

1. On the **File** menu, point to **Add Project** and then click **New Project** to open the **Add New Project** dialog box.
2. Select the Visual Basic projects node, and click **Windows Application**.
3. In the **Name** box, type **Test**.
4. In Solution Explorer, right-click the **References** node for your test project, then select **Add Reference** from the shortcut menu to display the **Add Reference** dialog box.
5. Click the **Projects** tab.
6. Double-click your project, and note that it now appears in the **Selected Components** pane of the dialog box.

After you have added your reference, you should add your new control to the Toolbox.

To add your control to the Toolbox

1. Right-click the Toolbox and choose **Add/Remove Items** from the shortcut menu.

   The **Customize Toolbox** dialog box opens.

2. Choose the **.NET Framework Components** tab and click **Browse**.
3. Browse to the ValueButtonLib\bin folder and select ValueButton.dll.

   ValueButton appears in the list of components in the **Customize Toolbox** dialog box.

4. In the **Customize Toolbox** dialog box, check the box next to ValueButton and close the window.

   The ValueButton is added to the tab of the Toolbox that was selected.

To add your control to the form

1. In Solution Explorer, right-click **Form1.vb** and choose **View Designer** from the shortcut menu.
2. In the Toolbox, scroll down until you come to the icon labeled **ValueButton**. Double-click this icon.

   A **ValueButton** appears on the form.

3. Right-click the **ValueButton** and select **Properties** from the shortcut menu.
4. In the Properties window, examine the properties of this control. Note that they are identical to the properties exposed by a standard button, except that there is an additional property, **ButtonValue**.
5. Set the **ButtonValue** property to **5**.
6. In the **Windows Forms** tab of the Toolbox, double-click **Label** to add a **Label** control to your form.
7. Relocate the label to the center of the form.

8. Double-click **ValueButton1**.

   The Code Editor opens to the **ValueButton1_Click** event.

9. Type the following line of code.

```
Label1.Text = CStr(ValueButton1.ButtonValue)
```

10. In Solution Explorer, right-click **Test**, and choose **Set as Startup Project** from the shortcut menu.
11. From the **Debug** menu, select **Start**.

    Form1 appears.

12. Click **Valuebutton1**.

    The numeral '5' is displayed in Label1, demonstrating that the ButtonValue property of your inherited control has been passed to Label1 via the ValueButton1_Click method. Thus your ValueButton control inherits all the functionality of the standard Windows Forms button, but exposes an additional, custom property.

Walkthrough: Authoring a User Control With Visual Basic .NET | Displaying Your Control in the Customize Toolbox Dialog Box | Developing Windows Forms Controls | Inheritance

Walkthrough: Inheriting from a Windows Forms Control with Visual C#

Visual C# .NET provides you with the ability to create powerful custom controls through *inheritance*. Through inheritance you are able to create controls that retain all of the inherent functionality of standard Windows Forms controls but also incorporate custom functionality. In this walkthrough, you will create a simple inherited control called ValueButton. This button will inherit functionality from the standard Windows Forms button, and will expose a custom property called ButtonValue.

Creating the Project

When you create a new project, you specify its name in order to set the root namespace, assembly name, and project name, and to ensure that the default component will be in the correct namespace.

To create the ValueButtonLib control library and the ValueButton control

1. On the **File** menu, point to **New** and then click **Project** to open the **New Project** dialog box.
2. Select the **Windows Control Library** project template from the list of C# Projects, and type **ValueButtonLib** in the **Name** box.

   > **Note** The Windows Control Library template is not available in the Standard Edition of Visual C# .NET. For more information, see Visual C# Standard Edition Features.

   The project name, ValueButtonLib, is also assigned to the root namespace by default. The root namespace is used to qualify the names of components in the assembly. For example, if two assemblies provide components named ValueButton, you can specify your ValueButton component using `ValueButtonLib.ValueButton`. For more information, see Components and Assemblies.

3. In Solution Explorer, right-click **UserControl1.cs** and select **View Code** from the shortcut menu.
4. Locate the **class** statement, `public class UserControl1`, and change **UserControl1** to **ValueButton** to change the name of the component.
5. Locate the Constructor, `public UserControl1()` and change it to `public ValueButton()`.
6. In the Class statement, change the type from which this control inherits from **System.Windows.Forms.UserControl** to **System.Windows.Forms.Button.** This allows your inherited control to inherit all the functionality of the **Button** control.
7. In Solution Explorer, click **UserControl1.cs** and in the Properties window, change the **FileName** property to **ValueButton.cs**.
8. From the **File** menu, choose **Save All** to save the project.

   Note that a designer is no longer available. Because the **Button** control does its own painting, you are unable to modify its appearance in the designer. Its visual representation will be exactly the same as that of the class it inherits from (that is, **Button**) unless modified in the code.

Adding a Property to Your Inherited Control

One possible use of inherited Windows Forms controls is the creation of controls that are identical in look and feel of standard Windows Forms controls, but expose custom properties. In this section, you will add a property called ButtonValue to your control.

To add the Value property

1. In Solution Explorer, right-click **ValueButton.cs**, and then click **View Code** from the shortcut menu.
2. Locate the **class** statement. Immediately after the {, type the following code:

```
// Creates the private variable that will store the value of your
// property.
private int varValue;
// Declares the property.
public int ButtonValue
{
   // Sets the method for retrieving the value of your property.
   get
   {
```

```
        return varValue;
    }
    // Sets the method for setting the value of your property.
    set
    {
        varValue = value;
    }
}
```

This code sets the methods by which the ButtonValue property is stored and retrieved. The **get** statement sets the value returned to the value that is stored in the private variable **varValue**, and the **set** statement sets the value of the private variable by use of the **value** keyword.

3. From the **File** menu, choose **Save All** to save the project.

Testing Your Control

Controls are not stand-alone projects; they must be hosted in a container. In order to test your control, you must provide a test project for it to run in. You must also make your control accessible to the test project by building (compiling) it. In this section, you will build your control and test it in a Windows Form.

To build your control

- On the **Build** menu, click **Build**.

  The build should be successful with no compiler errors or warnings.

To create a test project

1. On the **File** menu, point to **Add Project** and then click **New Project** to open the **Add New Project** dialog box.
2. Select the Visual C# projects node, and click Windows Application.
3. In the **Name** box, type **Test**.
4. In Solution Explorer, right-click the **References** node for your test project, then select **Add Reference** from the shortcut menu to display the **Add Reference** dialog box.
5. Click the tab labeled **Projects**.
6. Double-click the ValueButtonLib project, and note that it now appears in the **Selected Components** pane.

   After you have added your reference, you should add your new control to the toolbox. If your control already appears in the toolbox, you should skip the next section.

To add your control to the toolbox

1. Right-click the Toolbox and choose **Add/Remove Items** from the shortcut menu.

   The **Customize Toolbox** dialog box opens.

2. Choose the **.NET Framework Components** tab and click **Browse**. Browse to the ValueButtonLib\bin\debug folder and select ValueButton.dll.

   ValueButton appears in the list of components in the **Customize Toolbox** dialog box.

3. In the **Customize Toolbox** dialog box, check the box next to ValueButton and close the window.

   The ValueButton is added to the tab of the Toolbox that was selected.

To add your control to the form

1. In Solution Explorer, right-click **Form1.cs** and choose **View Designer** from the shortcut menu.
2. In Toolbox, scroll down until you come to the icon labeled **ValueButton**. Double-click this icon.

   A **ValueButton** appears on the form.

3. Right-click the **ValueButton** and select **Properties** from the shortcut menu.
4. In the Properties window, examine the properties of this control. Note that they are identical to the properties exposed by a standard button, except that there is an additional property, **ButtonValue**.
5. Set the **ButtonValue** property to **5**.

6. In the **Windows Forms** tab of the Toolbox, double-click **Label** to add a **Label** control to your form.
7. Relocate the label to the center of the form.
8. Double-click **valueButton1**.

   The Code Editor opens to the **valueButton1_Click** event.

9. Type the following line of code.

```
label1.Text = valueButton1.ButtonValue.ToString();
```

10. In Solution Explorer, right-click **Test**, and choose **Set as Startup Project** from the shortcut menu.
11. From the **Debug** menu, select **Start**.

    Form1 appears.

12. Click **valueButton1**.

The numeral '5' is displayed in Label1, demonstrating that the ButtonValue property of your inherited control has been passed to Label1 via the ValueButton1_Click method. Thus your ValueButton control inherits all the functionality of the standard Windows Forms button, but exposes an additional, custom property.

Control Type Recommendations

The .NET Framework gives you power to develop and implement new controls. In addition to the familiar user control, you will now find that you are able to write custom controls that perform their own painting, and are even able to extend the functionality of existing controls through inheritance. Deciding which type of control to create can be confusing. This section highlights the differences between the various types of controls from which you can inherit, and gives considerations regarding the type to choose for your project.

> **Note** If you want to author a control to use on Web Forms, see Developing ASP.NET Server Controls.

Inheriting from a Windows Forms Control

You can derive an inherited control from any existing Windows Forms control. This approach allows you to retain all of the inherent functionality of a Windows Forms control, and to then extend that functionality by adding custom properties, methods, or other functionality. For example, you might create a control derived from **TextBox** that can accept only numbers and automatically converts input into a value. Such a control might contain validation code that was called whenever the text in the text box changed, and could have an additional property, Value. In some controls, you can also add a custom appearance to the graphical interface of your control by overriding the **OnPaint** method of the base class.

Inherit from a Windows Forms control if:

- Most of the functionality you need is already identical to an existing Windows Forms control.
- You do not need a custom graphical interface, or you want to design a new graphical front end for an existing control.

Inheriting from the UserControl Class

A user control is a collection of Windows Forms controls encapsulated into a common container. The container holds all of the inherent functionality associated with each of the Windows Forms controls and allows you to selectively expose and bind their properties. An example of a user control might be a control built to display customer address data from a database. This control would include several textboxes to display each field, and button controls to navigate through the records. Data-binding properties could be selectively exposed, and the entire control could be packaged and reused from application to application.

Inherit from the **UserControl** class if:

- You want to combine the functionality of several Windows Forms controls into a single reusable unit.

Inheriting from the Control Class

Another way to create a control is to create one substantially from scratch by inheriting from **Control**. The **Control** class provides all of the basic functionality required by controls (for example, events), but no control-specific functionality or graphical interface. Creating a control by inheriting from the **Control** class requires a lot more thought and effort than inheriting from user control or an existing Windows Forms control. The author must write code for the **OnPaint** event of the control, as well as any functionality specific code that is needed. Greater flexibility is allowed, however, and you can custom tailor a control to suit your exact needs. An example of a custom control is a clock control that duplicates the look and action of an analog clock. Custom painting would be invoked to cause the hands of the clock to move in response to **Tick** events from an internal timer component.

Inherit from the **Control** class if:

- You want to provide a custom graphical representation of your control.
- You need to implement custom functionality that is not available through standard controls.

Walkthrough: Inheriting from a Windows Forms Control with Visual Basic .NET | Authoring Controls for Windows Forms

Authoring Controls for Windows Forms

A control represents a graphical link between the user and the program. A control can provide or process data, accept user input, respond to events, or perform any number of other functions that connect the user and the application. Because a control is essentially a component with a graphical interface, it can serve any function that a component does, as well as providing user interaction. Controls are created to serve specific purposes, and authoring controls is just another programming task. With that in mind, the following steps represent an overview of the control authoring process. Links provide additional information on the individual steps.

> **Note** If you want to author a custom control to use on Web Forms, see Developing ASP.NET Server Controls.

To author a control

1. Determine what you want your control to accomplish, or what part it will play in your application. Factors to consider are:
   - What kind of graphical interface do I need?
   - What specific user interactions will this control handle?
   - Is the functionality I need approached by any existing controls?
   - Can I get the functionality I need by combining several Windows Forms controls?
2. If you need an object model for your control, determine how functionality will be distributed throughout the object model, and divide up functionality between the control and any subobjects. An object model may be useful if you are planning a complex control, or wish to incorporate several functionalities.
3. Determine the type of control (for example, user control, custom control, inherited Windows Forms control) you need. For details, see Control Type Recommendations.
4. Express functionality as properties, methods, and events of the control and its subobjects or subsidiary structures, and assign appropriate access levels (public, protected, and so on). For more information, see Properties, Methods, and Events for Custom Controls.
5. If you need custom painting for your control, add code for it. For details, see Custom Control Painting and Rendering.
6. Create a new project (such as a Windows Application) so that you can test and debug your control.

   Another project is required because controls cannot be run as stand-alone projects. They must be placed into a container before they can be tested. This process is demonstrated as part of Walkthrough: Authoring a User Control With Visual Basic .NET.
7. As you add each feature, add features to your test project to exercise the new functionality.
8. Repeat, refining the design.
9. Package and deploy your control. For details, see Merge Module Projects.

Authoring User Controls

User controls can be employed in many ways. You can author them as part of a Windows desktop application project, and use them only on forms in the project. Or you can author them in a Windows Control Library project, compile the project into an assembly, and use the controls in other projects. You can even inherit from them, and use visual inheritance to customize them quickly for special purposes.

> **Note** If you want to author a user control to use on Web Forms, see Developing ASP.NET Server Controls.

To author a user control

1. Open a new **Windows Application** project.
2. On the **Project** menu, click **Add User Control**.
3. Add controls from the **Toolbox** to the user control surface.
4. Place code in event procedures, to handle events raised by the UserControl or by its constituent controls.
5. Close the designer for the user control, and save the file.
6. Give the class file (.vb or .cs file) the name you want the user control to have.
7. On the **Build** menu, click **Build**.

   The project must be built in order for user controls to appear in the **Toolbox**.

8. Use the **Windows Forms** tab of the **Toolbox** to add instances of your control to Form1.

To author a control class library

1. Open a new **Windows Control Library** project.

   By default, the project contains a user control.

   > **Note** The Windows Control Library template is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

2. Add controls and code as described in the procedure above.
3. Choose a control you do not want inheriting classes to change, and set the **Modifiers** property of this control to **Private**.
4. Build the DLL.

To inherit from a user control in a control class library

1. Open a **Windows Application** project.
2. In **Solution Explorer**, right-click the **References** folder and choose **Add Reference** to open the **Add Reference** dialog box.
3. Select the **Projects** tab and double-click your DLL.
4. On the **Project** menu, click **Add Inherited Control**.
5. In the **Inheritance Picker** dialog box, double-click the control you want to inherit from.
6. In the Add New Item dialog box, click Open (Inherited User Control is already selected).
7. In the **Inheritance Picker** dialog box, browse to and double-click the control you want to inherit from.

   A new control is added to your project.

8. Open the visual designer for the new control and add additional constituent controls.

   You can see the constituent controls that were inherited from the user control in your DLL, and you can alter the properties of controls whose **Modifiers** property is **Public**. You cannot change the properties of the control whose **Modifiers** property is **Private**.

Walkthrough: Authoring a User Control With Visual Basic .NET | Walkthrough: Inheriting from a Windows Forms Control with Visual Basic .NET | Control Type Recommendations | Authoring Controls for Windows Forms

Inheriting from the UserControl Class

If you want to combine the functionality of one or more Windows Forms controls with custom code, then you should create a *user control*. User controls combine rapid control development with standard Windows Forms control functionality and the versatility created by adding custom properties and methods. When creating a user control, you are presented with a visible designer, upon which you may place standard Windows Forms controls. These controls retain all of their inherent functionality, as well as the look and feel of standard controls, but once they are built into the user control they are no longer available to the developer through code. The user control does its own painting and also handles all of the basic functionality associated with controls.

To create a user control

1. Create a new **Windows Control Library** project.

   A new project is created with a blank user control.

   > **Note** The Windows Control Library template is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

2. Drag controls from the Windows Forms tab of the Toolbox onto your designer.
3. These controls should be positioned and designed as you want them to appear in the final user control. If you want to allow developers to access the constituent controls, you must declare them as public, or selectively expose properties of the constituent control. For details, see Exposing Properties of Constituent Controls.
4. Implement any custom methods or properties that your control will incorporate. For details, see Properties, Methods, and Events for Custom Controls.
5. Save and test your control.

See Also

Inheriting from the Control Class | Inheriting from Existing Windows Forms Controls | Authoring Controls for Windows Forms | Troubleshooting Inherited Event Handlers in Visual Basic .NET

Inheriting from the Control Class

If you want to create a completely custom control to use on a Windows Form, the class to inherit from is **Control**. While inheriting from the **Control** class requires greater planning and implementation, it also makes available the largest range of options. When inheriting from **Control**, you inherit the very basic functionality that makes controls work. The functionality inherent in the **Control** class handles user input through the keyboard and mouse, defines the bounds and size of the control, provides a windows handle, and provides message handling and security. It does not incorporate any painting (the actual rendering of the graphical interface of the control), nor does it incorporate any specific user interaction functionality. The author must provide all of these aspects through custom code.

To create a custom control

1. Create a new **Windows Application** or **Windows Control Library** project.

   > **Note** The Windows Control Library template is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

2. From the **Project** menu, choose **Add Inherited Control**.

   The **Add New Item** dialog box appears.

3. In the **Add New Item** dialog box, click **Custom Control**.

   A new custom control is added to your project.

4. Open the Code Editor for your **CustomControl**.
5. Locate the **OnPaint** method, which will be empty except for a call to the **OnPaint** of the base class.
6. Modify the code to incorporate any custom painting you want for your control.

   For details on writing code to render graphics for controls, see Custom Control Painting and Rendering.

7. Implement any custom methods, properties, or events that your control will incorporate. For more information, see Properties, Methods, and Events for Custom Controls.
8. Save and test your control.

See Also

Inheriting from the UserControl Class | Inheriting from Existing Windows Forms Controls | Authoring Controls for Windows Forms | Troubleshooting Inherited Event Handlers in Visual Basic .NET

Inheriting from Existing Windows Forms Controls

If you want to extend the functionality of an existing control, you can create a control derived from an existing control through inheritance. When inheriting from an existing control, you inherit all of the functionality and visual properties of that control. For instance, if you were creating a control that inherited from **Button**, your new control would look and act exactly like a standard **Button** control. You could then extend or modify the functionality of your new control through the implementation of custom methods and properties. In some controls, you can also change the visual appearance of your inherited control by overriding its **OnPaint** method.

To create an inherited control

1. Create a new **Windows** project.

   This project can be of any type, such as a **Windows Application** project or a **Windows Control Library** project. If you choose a **Windows Control Library**, you may use the blank control provided and skip steps 2 and 3.

2. From the **Project** menu, choose **Add Inherited Control**.

   The **Add New Item** dialog box appears.

3. In the **Add New Item** dialog box, double-click **Custom Control**.

   A new custom control is added to your project.

4. In the Code Editor, locate the line that specifies **Control** as the base class to inherit from. Change the name of the base class to the name of the control from which you want to inherit.

   For example, if you want to inherit from **Button**, the line would read:

```
' Visual Basic
Inherits System.Windows.Forms.Button

// C#
public class CustomControl1 : System.Windows.Forms.Button
```

5. Implement any custom methods or properties that your control will incorporate. For further information see Properties, Methods, and Events for Custom Controls.
6. If you want to modify the graphical appearance of your control, override the **OnPaint** method.

   Note Overriding **OnPaint** will not allow you to modify the appearance of all controls. Those controls that have all of their painting done by Windows (for example, **Textbox**) never call their **OnPaint** method, and thus will never use the custom code. Please refer to the documentation of the particular control you wish to modify to see if the **OnPaint** method is available. If a control does not have **OnPaint** listed as a member method, then you cannot alter its appearance by overriding this method. For more information on custom painting, see Custom Control Painting and Rendering.

```
' Visual Basic
Protected Overrides Sub OnPaint(ByVal pe As _
   System.Windows.Forms.PaintEventArgs)
   MyBase.OnPaint(pe)
   ' Insert code to do custom painting. If you want to completely
   ' change the appearance of your control, do not call
   ' MyBase.OnPaint(pe).
End Sub

// C#
protected override void OnPaint(PaintEventArgs pe)
{
   // Do not call base.OnPaint if you want to completely
   // control the appearance of the control.
   base.OnPaint(pe);
```

```
    // Insert code to do custom painting.
  }
```

7. Save and test your control.

Inheriting from the Control Class | Inheriting from the UserControl Class | Authoring Controls for Windows Forms | Troubleshooting Inherited Event Handlers in Visual Basic .NET

Properties, Methods, and Events for Custom Controls

A custom control is any control that is created by the user, be it derived from the **UserControl** class, the **Control** class, or an existing Windows Forms control. Your control provides front-end functionality through its graphical interface, but provides back-end functionality through its methods, properties, and events. Methods are the actions a user can tell your control to execute. Properties and member variables are data a user of your control can get or set. Events are notifications that something interesting has happened to your component.

Adding properties and methods is easy — a method is any public procedure you declare in your control class; a property can be declared using a **Property** statement in Visual Basic, or implemented as a public member variable in C#.

The following topics examine the issues you should be aware of when declaring properties and methods in a control.

In This Section

Exposing Properties of Constituent Controls
Describes how to expose the properties of a constituent control to developers using your user control.

Method Implementation in Custom Controls
Provides conceptual information on implementing methods in your control and overloading methods.

Related Sections

Event Implementation for Components and Custom Controls with Visual Basic
Provides conceptual information for Visual Basic developers on events in your user control.

Developing ASP.NET Server Controls
Provides links to topics about how to create methods and properties for custom server controls that work with Web Forms.

Exposing Properties of Constituent Controls

The controls that make up a user control are called *constituent controls*. These controls are normally declared private, and thus cannot be accessed by the developer. If you want to make properties of these controls available to future users, you must expose them to the user. A property of a constituent control is exposed by creating a property in the user control, and using the **Get** and **Set** accessors of that property to effect the change in the private property of the constituent control.

Consider a hypothetical user control with a constituent button named MyButton. In this example, when the user requests the ConstituentButtonBackColor property, the value stored in the **BackColor** property of MyButton is delivered. When the user assigns a value to this property, that value is automatically passed to the **BackColor** property of MyButton and the **Set** code will execute, changing the color of MyButton.

The following example shows how to expose the **BackColor** property of the constituent button:

```
' Visual Basic
Public Property ButtonColor() as System.Drawing.Color
   Get
      Return MyButton.BackColor
   End Get
   Set(Value as System.Drawing.Color)
      MyButton.BackColor = Value
   End Set
End Property

// C#
public Color ButtonColor
{
   get
   {
      return(myButton.BackColor);
   }
   set
   {
      myButton.BackColor = value;
   }
}
```

To expose a property of a constituent control

1. In the Code Editor for your user control, create a public property.
2. In the **Get** section of the property, write code that retrieves the value of the property you want to expose.
3. In the **Set** section of the property, write code that passes the value of the property to the exposed property of the constituent control.

Walkthrough: Authoring a User Control With Visual Basic .NET

Method Implementation in Custom Controls

A method is implemented in a control in the same manner a method would be implemented in any other component.

In Visual Basic, if a method is required to return a value, it is implemented as a **Public Function**. If no value is returned, it is implemented as a **Public Sub**. Methods are declared using the following syntax:

```
' Visual Basic
Public Function ConvertMatterToEnergy(Matter as Integer) As Integer
   ' Conversion code goes here.
End Function
```

Because functions return a value, they must specify a return type, such as integer, string, object, and so on. The arguments **Function** or **Sub** procedures take, if any, must also be specified.

C# makes no distinction between functions and procedures, as Visual Basic does. A method either returns a value or returns void. The syntax for declaring a C# public method is:

```
// C#
public int ConvertMatterToEnergy(int matter)
{
   // Conversion code goes here.
}
```

When you declare a method, declare all of its arguments as explicit data types whenever possible. Arguments that take object references should be declared as specific class types — for example, **As Widget** instead of **As Object**. In Visual Basic, the default setting **Option Strict** automatically enforces this rule.

Typed arguments allow many developer errors to be caught by the compiler, rather than at run time. The compiler always catches errors, whereas run-time testing is only as good as the test suite.

Overloaded Methods

If you want to allow users of your control to supply different combinations of parameters to a method, provide multiple overloads of the method, using explicit data types. Avoid creating parameters declared **As Object** that can contain any data type, as this can lead to errors that might not be caught in testing.

> **Visual Basic Note** The universal data type in the common language runtime is **Object** rather than **Variant**. **Variant** has been removed from the language. For details, see Universal Data Type Changes in Visual Basic.

For example, the **Spin** method of a hypothetical Widget control might allow either direct specification of spin direction and speed, or specification of another Widget object from which angular momentum is to be absorbed:

```
' Visual Basic
Overloads Public Sub Spin( _
   ByVal SpinDirection As SpinDirectionsEnum, _
   ByVal RevolutionsPerSecond As Double)
   ' Implementation code here.
End Sub
Overloads Public Sub Spin(ByVal Driver As Widget) _
   ' Implementation code here.
End Sub

// C#
public void Spin(SpinDirectionsEnum spinDirection, double revolutionsPerSecond)
{
   // Implementation code here.
}

public void Spin(Widget driver)
{

Custom Control Painting and Rendering

Custom painting of controls is one of the many complicated tasks made easy by the .NET Framework. When authoring a custom control, you have many options regarding your control's graphical appearance. If you are authoring a control that inherits from the Control Class, you must provide code that allows your control to render its graphical representation. If you are creating a user control by inheriting from the UserControl Class, or are inheriting from one of the Windows Forms controls, you may override the standard graphical representation and provide your own graphics code. If you want to provide custom rendering for the constituent controls of a UserControl you are authoring, your options become more limited, but still allow a wide range of graphical possibilities for your controls and applications.

In this Section

User-Drawn Controls
Gives an overview of the steps involved in writing and overriding rendering code for your control.
Constituent Controls
Describes how to implement custom rendering code for constituent controls in your user controls and forms.

Control Authoring for Windows Forms
Provides links to topics about creating your own custom control.

User-Drawn Controls

The .NET Framework provides you with the ability to easily develop your own controls. You can create a user control, which is a set of standard controls bound together by code, or you can design your own control from the ground up. You can even use inheritance to create a control that inherits from an existing control and add to its inherent functionality. Whatever approach you use, the .NET Platform provides the functionality to draw a custom graphical interface for any control you create.

Painting of a control is accomplished by the execution of code in the control's Control.OnPaint Method. The single argument of the **OnPaint** method is a **PaintEventArgs** object that provides all of the information and functionality required to render your control. The **PaintEventArgs** provides as properties two principal objects that will be used in the rendering of your control:

- **ClipRectangle** object - the rectangle that represents the part of the control that will be drawn. This can be the entire control, or part of the control depending on how the control is drawn.
- **Graphics** object - encapsulates several graphics-oriented objects and methods that provide the functionality necessary to draw your control.

For more information on the **Graphics** object and how to use it, see Creating Graphical Images with GDI+.

The **OnPaint** event is fired whenever the control is drawn or refreshed on the screen, and the **ClipRectangle** object represents the rectangle in which painting will take place. If the entire control needs to be refreshed, the **ClipRectangle** will represent the size of the entire control. If only part of the control needs to be refreshed, however, the **ClipRectangle** object will represent only the region that needs to be redrawn. An example of such an example would be when a control was partially obscured by another control or form in the user interface.

When inheriting from the **Control** class, you must override the **OnPaint** method and provide graphics-rendering code within. If you want to provide a custom graphical interface to a user control or an inherited control, you can also do so by overriding the **OnPaint** method. An example is shown below:

```
' Visual Basic
Protected Overrides Sub OnPaint(ByVal pe As PaintEventArgs)
   ' Call the OnPaint method of the base class.
   MyBase.OnPaint(pe)

   ' Declare and instantiate a drawing pen.
   Dim myPen As System.Drawing.Pen = New System.Drawing.Pen(Color.Aqua)

   ' Draw an aqua rectangle in the rectangle represented by the control.
   pe.Graphics.DrawRectangle(myPen, New Rectangle(Me.Location, Me.Size))
End Sub

// C#
protected override void OnPaint(PaintEventArgs pe)
{
   // Call the OnPaint method of the base class.
   base.OnPaint(pe);

   // Declare and instantiate a new pen.
   System.Drawing.Pen myPen = new System.Drawing.Pen(Color.Aqua);

   // Draw an aqua rectangle in the rectangle represented by the control.
   pe.Graphics.DrawRectangle(myPen, new Rectangle(this.Location,
      this.Size));
}
```

The preceding example demonstrates how to render a control with a very simple graphical representation. It calls the **OnPaint** method of the base class, it creates a **Pen** object with which to draw, and finally draws an ellipse in the rectangle determined by the **Location** and **Size** of the control. Although most rendering code will be significantly more complicated than this, this example demonstrates the use of the **Graphics** object contained within the **PaintEventArgs** object. Note that if you are inheriting from a class that already has a graphical representation, such as **UserControl** or **Button**, and you do not wish to incorporate that representation into your rendering, you should not call your base class's **OnPaint** method.

The code in the **OnPaint** method of your control will execute when the control is first drawn, and whenever it is refreshed. To ensure that your control is redrawn every time it is resized, add the following line to the constructor of your control:

```
' Visual Basic
SetStyle(ControlStyles.ResizeRedraw, True)

//C#
SetStyle(ControlStyles.ResizeRedraw, true);
```

Creating Graphical Images with GDI+ | Constituent Controls | ControlStyles Enumeration

Constituent Controls

The controls that make up a user control, or *constituent controls* as they are termed, are relatively inflexible when it comes to custom graphics rendering. All Windows Forms controls handle their own rendering through their own **OnPaint** method. Because this method is protected, it is not accessible to the developer, and thus cannot be prevented from executing when the control is painted. This does not mean, however, that you cannot add code to affect the appearance of constituent controls. Additional rendering can be accomplished by adding an event handler. For example, suppose you were authoring a UserControl with a button named MyButton. If you wished to have additional rendering beyond what was provided by the Button Class, you would add code to your user control similar to the following:

```
' Visual Basic
Public Sub MyPaint(ByVal sender as Object, e as PaintEventArgs) Handles _
   MyButton.Paint
   'Additional rendering code goes here
End Sub

// C#
// Add the event handler to the button's Paint event.
MyButton.Paint +=
   new System.Windows.Forms.PaintEventHandler (this.MyPaint);
// Create the custom painting method.
protected void MyPaint (object sender,
System.Windows.Forms.PaintEventArgs e)
{
   // Additional rendering code goes here.
}
```

> **Note** Some Windows Forms controls, such as **TextBox**, are painted directly by Windows. In these instances, the **OnPaint** method is never called, and thus the above example will never be called.

This creates a method that executes every time the MyButton.Paint event executes, thereby adding additional graphical representation to your control. Note that this does not prevent the execution of MyButton.OnPaint, and thus all of the painting usually performed by a button will still be performed in addition to your custom painting. For details about GDI+ technology and custom rendering, see the Creating Graphical Images with GDI+. If you wish to have a unique representation of your control, your best course of action is to create an inherited control, and to write custom rendering code for it. For details, see User-Drawn Controls.

Walkthrough: Inheriting from a Windows Forms Control with Visual Basic .NET

Making Your Control Invisible at Run Time

There are times when you might want to create a user control that is invisible at run time. For example, a control that is an alarm clock might be invisible except when the alarm was sounding. This is easily accomplished by setting the **Visible** property. If the **Visible** property is **true**, your control will appear as normal. If **false**, your control will be hidden. Although code in your control may still run while invisible, you will not be able to interact with the control through the user interface. If you want to create an invisible control that still responds to user input (for example, mouse clicks), you should create a transparent control. For more information, see Giving Your Control a Transparent Background.

To make your control invisible at run time

- Set the **Visible** property to **false**.

```
' Visual Basic
' To set the Visible property from within your object's own code.
Me.Visible = False
' To set the Visible property from another object.
myControl1.Visible = False

// C#
// To set the Visible property from within your objects own code.
this.Visible = false;
// To set the Visible property from another object.
myControl1.Visible = false;
```

Aligning Your Control to the Edges of Forms

You can make your control align to the edge of your forms by setting the Dock Property. This property designates where your control resides in the form. The **Dock** property can be set to the following values:

Setting	Effect on your control
DockStyle.Bottom	Docks to the bottom of the form.
DockStyle.Fill	Fills all remaining space in the form.
DockStyle.Left	Docks to the left side of the form.
DockStyle.None	Does not dock anywhere, and it appears at the location specified by its Location Property.
DockStyle.Right	Docks to the right side of the form.
DockStyle.Top	Docks to the top of the form.

These values can be set in code, but they are usually set at design time in the Properties window.

To set the Dock property for your control at run time

- Set the **Dock** property to the appropriate value in code.

```
' Visual Basic
' To set the Dock property internally.
Me.Dock = DockStyle.Top
' To set the Dock property from another object.
UserControl1.Dock = DockStyle.Top

// C#
// To set the Dock property internally.
this.Dock = DockStyle.Top;
// To set the Dock property from another object.
UserControl1.Dock = DockStyle.Top;
```

To set the Dock property for your control at design time

1. In the designer, select your control.
2. In the Properties window, click the drop-down box next to the **Dock** property.

   A graphical interface representing the six possible **Dock** settings is displayed.

3. Choose the appropriate setting.

   Your control will now dock in the manner specified by the setting.

Providing a Toolbox Bitmap for Your Control

You might want to have a special icon for your control appear in the Toolbox. You can specify a particular image by using the ToolboxBitmapAttribute Class. This class is an *attribute*, a special kind of class you can attach to other classes. For more information on attributes, see Attributes Overview for Visual Basic and Introduction to Attributes for C#.

Using the **ToolboxBitmapAttribute**, you can specify a **String** that indicates the path and file name for a 16 by 16 pixel bitmap. This bitmap then appears next to your control when added to the Toolbox. You can also specify a **Type**, in which case the bitmap associated with that type is loaded. If you specify both a **Type** and a **String**, the control searches for an image resource with the name specified by the **String** parameter in the assembly containing the type specified by the **Type** parameter.

To specify a Toolbox bitmap for your control

- Add the **ToolBoxBitmapAttribute** to the class declaration of your control before the **Class** keyword for Visual Basic, and above the class declaration for Visual C#.

```
' Visual Basic
' Specifies the bitmap associated with the Button type.
<ToolboxBitmap(GetType(Button))> Class MyControl1
' Specifies a bitmap file.
End Class
<ToolboxBitmap("C:\Documents and Settings\Joe\MyPics\myImage.bmp")> _
   Class MyControl2
End Class
' Specifies a type that indicates the assembly to search, and the name
' of an image resource to look for.
<ToolboxBitmap(GetType(MyControl), "MyControlBitmap")> Class MyControl
End Class

// C#
// Specifies the bitmap associated with the Button type.
[ToolboxBitmap(typeof(Button))]
class MyControl1 : UserControl
{
}
// Specifies a bitmap file.
[ToolboxBitmap(@"C:\Documents and Settings\Joe\MyPics\myImage.bmp")]
class MyControl2 : UserControl
{
}
// Specifies a type that indicates the assembly to search, and the name
// of an image resource to look for.
[ToolboxBitmap(typeof(MyControl), "MyControlBitmap")]
class MyControl : UserControl
{
}
```

Extender Provider Objects

An *extender provider* is a component that provides properties to other components. For example, when a ToolTip Component (Windows Forms) component is added to a form, it provides a property called **ToolTip** to each control on that form. The **ToolTip** property then appears in the Properties window for each control and allows the developer to set a value for this property at design time.

The property provided by the extender provider actually resides in the extender provider object itself and therefore is not a true property of the component it modifies. At design time, the property will appear in the Properties window for the component that is being modified. At run time, however, the property cannot be accessed through the component itself. In the following code example, a form has been created with a button called MyButton and a **ToolTip** control called MyToolTip, which provides a **ToolTip** property.

```
' Visual Basic
' This is an example of code that is NOT CORRECT!
Dim myString as String
myString = MyButton.ToolTip

// C#
// This is an example of code that is NOT CORRECT!
string myString;
myString = MyButton.ToolTip;
```

This syntax will generate a compile error because the compiler does not recognize **ToolTip** as a property of MyButton, because the property is actually provided by MyToolTip. The following example shows how to correctly access that property:

```
' Visual Basic
Dim myString as String
myString = MyToolTip.GetToolTip(MyButton)

// C#
string myString;
myString = MyToolTip.GetToolTip(MyButton);
```

The extender provider is a class, and as such can have its own properties and methods. In order to designate a property as the property to be provided to other components, you apply the ProvidePropertyAttribute attribute at the class level. This attribute specifies the name of the property to provide and the type of object it can provide that property to. By convention, the property provided is not implemented as a property, but rather as a pair of methods. These methods must have "Get" and "Set" added to the beginning of the name of the property to be provided. The following example shows how.

```
' Visual Basic
Imports System.ComponentModel
<ProvideProperty("MyText", GetType(Control))> Public Class MyExtender
   <ExtenderProvidedProperty()> Public Function GetMyText(acontrol as _
      Control) as String
      ' Insert code to implement function.
   End Function
   Public Sub SetMytext (acontrol as Control)
      ' Insert code to implement function.
   End Function
End Class

// C#
using System.ComponentModel;
[ProvideProperty("MyText", typeof("Control"))]
public class MyExtender
{
[ExtenderProvidedProperty()]
   public string GetMyText(Control acontrol)
   {
      // Insert code to implement method.
   }
   public void SetMyText(Control acontrol)
```

```
    {
       // Insert code to implement method.
    }
}
```

The implementation of the provided property will require a **Hashtable** or some other such collection object to record and retrieve the property values for each control. For details, see Implementing an Extender Provider.

Every extender class must also implement the IExtenderProvider Interface. That interface consists of a single method, **CanExtend**, which returns a Boolean value and indicates to the designer whether a component is a candidate to be extended or not. For example, you might want to create an extender that provides a property only to controls. The following example shows how to implement the **CanExtend** method:

```
' Visual Basic
Imports System.ComponentModel
Public Function CanExtend(ByVal extendee As Object) As Boolean _
   Implements IExtenderProvider.CanExtend
   If Typeof extendee Is Control Then
      Return True
   Else
      Return False
   End If
End Function

// C#
public bool CanExtend(object extendee)
{
   if (extendee is Control)
      return true;
   else
      return false;
}
```

IExtenderProvider Interface | Implementing an Extender Provider

Giving Your Control a Transparent Background

By default, controls do not support transparent backcolors. However, you can allow your control to have a background color that is opaque, transparent, or partially transparent by using the Control.SetStyle Method in the constructor. The **SetStyle** method of the **Control** class allows you to set particular style preferences for your controls, and can be used to enable or disable support for transparent backcolors.

To give your control a transparent backcolor

1. In the Code Editor for your control, locate the constructor.
2. Call the **SetStyle** method of your form in the constructor.

   ```
   ' Visual Basic
   SetStyle(ControlStyles.SupportsTransparentBackColor, True)

   // C#
   SetStyle(ControlStyles.SupportsTransparentBackColor, true);
   ```

   This will enable your control to support a transparent backcolor.

3. Beneath the line of code you added in step 1, add the following line. This will set your control's **BackColor** to **Transparent**.

   ```
   ' Visual Basic
   Me.BackColor = Color.Transparent

   // C#
   this.BackColor = Color.Transparent;
   ```

   Note that you can also create colors that are partially transparent using the **Color.FromArgb** method. For more information on colors, see Pens, Brushes, and Colors.

Displaying Your Control in the Customize Toolbox Dialog Box

As you develop and distribute controls, you might want those controls to appear in the **Customize Toolbox** dialog box, which is displayed when you customize the toolbox. You can enable your control to appear in this dialog box by either setting the appropriate registry key value or by installing your control to the Global Assembly Cache.

To display your control in the Customize Toolbox dialog box

- Install your control assembly to the Global Assembly Cache. For additional information, see Installing an Assembly into the Global Assembly Cache

  -or-

- Use the Windows utility **Regedit.exe** to create a registry key at HKEY_LOCAL_MACHINE\Software\Microsoft\Visual Studio\7.1\AssemblyFolders\<KeyName> and set the Default string value to the file location where your assembly is found. <KeyName> can be any value you prefer.

  > **Note** In Visual Studio .NET 2002, this key should be created at HKEY_LOCAL_MACHINE\Software\Microsoft\.NET\AssemblyFolders\<KeyName>.

Control Authoring for Windows Forms | Installing an Assembly into the Global Assembly Cache

Private Communication Between Components in Assemblies

At times, you might want to create components in an assembly that are exposed to other members of your assembly, but not to clients. For example, you might have an assembly that exposes Machine and Mechanism components to the user. Each of these components might in turn require Widget components, but the client application would have no need for a Widget component on its own.

A public component is accessible to all users of an assembly, including the client, but a private component is accessible only to other members of its namespace. Neither of these access modifiers allows the level of access that you require.

The solution is to use **Friend** (**internal** in C#) components. If a component is marked as **Friend** (**internal**), it can be freely accessed and instantiated by all other components in your assembly, but not by any users outside your assembly. The following example shows how to use the **Friend** (**internal**) access modifier.

```
' Visual Basic
Namespace Widgets
   ' This class will be accessible to other classes in the assembly,
   ' but not to client users.
   Friend Class Widget
      ' Insert code to implement the Widget class.
   End Class
End Namespace

' This namespace contains a class that will use a class in the Widgets
' namespace.
Namespace Mechanisms
   ' This class is accessible to client users, and can itself access the
   ' Widget class to create and contain instances of it.
   Public Class Mechanism
      Dim myWidget as New Widgets.Widget
      ' Insert code to implement additional functionality.
   End Class
End Namespace

// C#
namespace Widgets
{
   // This class will be accessible to other classes in the assembly,
   // but not to client users.
   internal class Widget
   {
      // Insert code to implement the Widget class.
   }
}

// The Mechanisms namespace declares Mechanism class that will contain an
// instance of the Widgets.Widget class.
namespace Mechanisms
{
   // This class is accessible to client users, and can itself access the
   // Widget class to create and contain instances of it.
   public class Mechanism
   {
      Widgets.Widget widget = new Widgets.Widget();
   }
}
```

Access Levels for Nested Classes

When assigning access levels to nested classes, there are additional considerations. For details, see Nested Classes in Components.

Accessing Members of Friend (internal) Components

Members of **Friend** (**internal**) components can be accessed according to the same access rules as members of a public

component, provided that the caller has access to the class. For example, a component named Mechanism that is a member of the same assembly as **Friend** (**internal**) component Widget can call the public method **Spin** of Widget, but an external user cannot. In practice, all public members of a **Friend** (**internal**) class have **Friend** (**internal**) access levels. Private members are accessible only from within the class itself.

Accessing Friend (internal) Members of Public Components

You might want to make methods or properties of a public component accessible only to members of your assembly. For example, a public Mechanism class might have a method named AddWidget. Any member of the assembly could invoke this method, but it would not make sense to allow the client to invoke it. In such a case, use the **Friend** (**internal**) access modifier on the method itself, and keep the access modifier on the class public.

> **Note** In the example below, the method AddWidget is accessible to all members of the assembly, but is not added to the public interface and cannot be called by client applications.

```
' Visual Basic
Public Class Mechanism
   Friend Sub AddWidget()
      ' Insert code to implement method.
   End Sub
   ' Insert code to implement the rest of the class.
End Class

// C#
public class Mechanism
{
   internal void AddWidget()
   {
      // Insert code to implement method.
   }
   // Insert code to implement the rest of the class.
}
```

COM Interoperability in Visual Basic and Visual C#

When you want to use COM objects and .NET objects in the same application, you need to address the differences in how the objects exist in memory. A .NET object is located in managed memory — the memory controlled by the common language runtime — and may be moved by the runtime as needed. A COM object is located in unmanaged memory and is not expected to move to another memory location. Visual Studio and the .NET Framework provide tools to control the interaction of these managed and unmanaged components. For more information about managed code, see Common Language Runtime.

In addition to using COM objects in .NET applications, you may also want to continue to develop COM objects using Visual Basic .NET or Visual C# .NET.

The links on this page provide information about the concepts and implementation details for interoperating between COM and .NET objects.

In the Visual Basic and Visual C# Documentation

COM Interop
: Provides links to topics covering COM interop in Visual Basic, including COM objects, ActiveX controls, Win32 DLLs, managed objects, and inheritance of COM objects.

COM Interop Part 1: C# Client Tutorial
: Shows how to use Visual C# to interoperate with COM objects.

COM Interop Part 2: C# Server Tutorial
: Describes using a Visual C# server with a C++ COM client.

COM Interop Wrapper Error
: Describes the consequences and options if the project system cannot create a COM interop wrapper for a particular component.

Additional Information

Interoperating with Unmanaged Code
: Briefly describes some of the interaction issues between managed and unmanaged code, and provides links for further study.

COM Wrappers
: Discusses runtime callable wrappers, which allow managed code to call COM methods, and COM callable wrappers, which allow COM clients to call .NET object methods.

Advanced COM Interop
: Provides links to topics covering COM interop with respect to wrappers, exceptions, inheritance, threading, events, conversions, and marshaling.

Automating Office Applications
: Provides information on using Microsoft Office and Visual Studio .NET as part of your business application.

Type Library Importer (Tlbimp.exe)
: Discusses the tool you can use to convert the type definitions found within a COM type library into equivalent definitions in a common language runtime assembly.

Creating Messaging Components

The **MessageQueue** component allows you to build complex messaging into your applications. Using **MessageQueue** component instances, you can easily send messages to and receive messages from any queue in your network.

XML Web services provide another means for incorporating messaging-type behavior into your applications. Using XML Web services, you can pass information back and forth between a Web application and any client.

The **MessageQueue** component allows you to easily incorporate message-based communication into your applications. Using this component and its associated language features, you can send and receive messages, explore existing queues, create and delete queues, and perform a variety of other operations using a simple programming model.

Introduction to Messaging

Microsoft Windows Message Queuing makes it easy for application developers to communicate with application programs quickly and reliably by sending and receiving messages. Messaging provides you with guaranteed message delivery and a robust, fail-safe way to carry out many of your business processes. For example, suppose you have a retail point-of-sale application that must run 24 hours a day, seven days a week. If the database system behind the application goes down your sales staff might need to start taking orders manually. Using Message Queuing, you can set up the system so that the orders that cannot be processed during the downtime are automatically put into a queue and processed as soon as the database comes back up.

In Microsoft Visual Studio .NET and the Microsoft .NET Framework SDK, you can use an instance of the **MessageQueue** component to quickly and easily connect to existing message queues, examine their contents, and send and receive messages. You can also use Server Explorer to view message queues on any server to which you have access, and to view information about the messages contained in these queues. You can add a queue from Server Explorer to your component's designer to automatically create a component that is configured to interact with the queue.

> **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

Interacting with Message Queues

Messaging and messages provide a powerful and flexible mechanism for interprocess communication between components of a server-based application. They have a number of advantages over direct calls between components, including:

- **Robustness** — Messages are considerably less affected by component failures than direct calls between components, because messages are stored in queues and remain there until processed appropriately. Messaging is similar to transaction processing, because message processing is guaranteed.
- **Message prioritization** — More urgent or important messages can be received before less important messages, so you can guarantee adequate response time for critical applications.
- **Offline capabilities** — Messages can be sent to temporary queues when they are sent and remain that way until they are successfully delivered. Users can continue to perform operations when access to the necessary queue is unavailable for whatever reason. In the meantime, additional operations can proceed as if the message had already been processed, because the message delivery is guaranteed when the network connection is restored.
- **Transactional messaging** — You can couple several related messages into a single transaction, ensuring that the messages are delivered in order, delivered only once, and are successfully retrieved from their destination queue. If any errors occur, the entire transaction is cancelled.
- **Security** — The Message Queuing technology on which the **MessageQueue** component is based uses Windows security to secure access control, provide auditing, and encrypt and authenticate the messages your component sends and receives.

Restrictions

Your system must meet the following requirements to develop **MessageQueue** components:

- To see queue information in Server Explorer or to access queues programmatically, you must install Message Queuing on your client computer.

  > **Note** When you install Message Queuing, you select the primary Message Queuing server to which you want to connect. You cannot view or manipulate queues that reside on another primary Message Queuing server.

- Message Queuing can be run in either a domain or a workgroup environment. In the context of Message Queuing, a domain environment includes domain controllers that provide a directory service such as Active Directory, and a workgroup environment is any environment that does not provide such a directory service.

Message Queues and Messaging Technology Backgrounder | Creating MessageQueue Component Instances

Message Queues and Messaging Technology Backgrounder

Microsoft Windows Message Queuing makes it easy for application developers to communicate with application programs quickly and reliably by sending and receiving messages. If you are unfamiliar with **MessageQueue** technology, this topic provides a brief overview of essential terms and concepts.

Key Concepts in Messaging

A *message* is a unit of data sent between two computers. A message can be very simple, consisting of just a string of text, or more complex, possibly involving embedded objects.

Messages are sent to queues. A *message queue* is a container that holds messages while they are in transit. The message queue manager acts as the middleman in relaying a message from its source to its destination. A queue's main purpose is to provide routing and guarantee the delivery of messages; if the recipient is not available when a message is sent, the queue holds the message until it can be successfully delivered.

Message Queuing, the Microsoft messaging technology, provides messaging and message queue facilities for any application and among any combination of computers that have Microsoft Windows installed, regardless of whether they are on the same network or online at the same time.

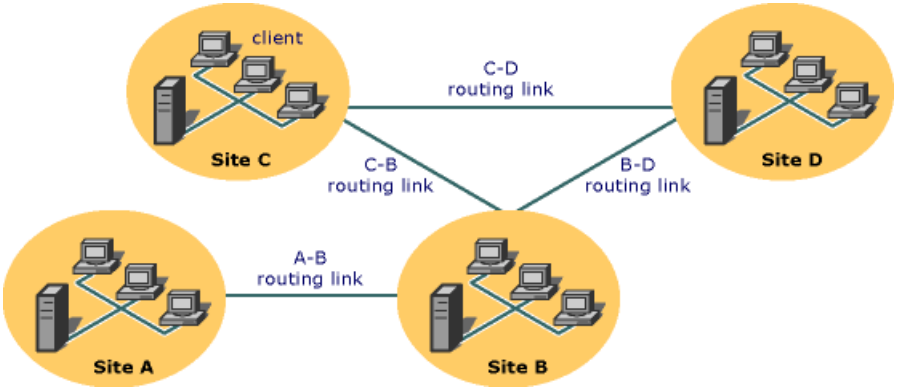
A *Message Queuing network* is any set of computers that are enabled to send messages back and forth to one another. Different computers in the network play different roles in ensuring that messaging proceeds smoothly. Some provide routing information to determine how messages are sent, some hold key information for the entire network, and some simply send and receive messages.

During Message Queuing setup, an administrator makes decisions about which servers can communicate with each other and sets up special roles for specific servers. The computers that make up this Message Queuing network are called *sites*, and they are connected to one another by *site links*. Each site link has an associated *cost*, determined by the administrator, that indicates how quickly messages can be passed across it.

The Message Queuing administrator also sets up one or more computers in the network to act as *routing servers*. A routing server makes decisions about how a message is delivered by looking at the cost of various site links and determining the quickest and most efficient way to deliver the message across multiple sites.

The following picture shows a typical configuration of Message Queuing sites and how they interact:

Message routing between sites



> **Tip** You do not need to worry about the details of message routing during development, because your Message Queuing network can be tuned by administrators for efficient message delivery.

Types of Queues

There are two main categories of queues — queues that you or other users of the network create, and system queues. User-created queues can be any of the following:

- *Public queues* are replicated throughout the Message Queuing network and can potentially be accessed by all of the sites connected by the network.
- *Private queues* are not published across the entire network. Instead they are available only on the local computer that contains them. Private queues can be accessed only by applications that know the full path name or label of the queue.
- *Administration queues* contain messages acknowledging the receipt of messages sent within a given Message Queuing network. You specify the administration queue you want your **MessageQueue** components to use, if any.

- *Response queues* contain response messages that are returned to the sending application when the message is received by the destination application. You specify the response queue you want your **MessageQueue** components to use, if any.

System-generated queues generally fall in one of the following categories:

- *Journal queues* optionally store copies of messages that you send and copies of messages removed from a queue. A single journal queue on each Message Queuing client stores copies of messages sent from that computer. On the server, a separate journal queue is created for each individual queue. This journal tracks messages removed from that queue.
- *Dead-letter queues* store copies of undeliverable or expired messages. If the expired or undeliverable message was a transactional message, it is stored in a special kind of dead-letter queue called a *transaction dead-letter queue*. Dead letters are stored on the computer on which the message expired. For more information on time-out periods and expired messages, see Default Message Properties.
- *Report queues* contain messages that indicate the route a message took to its destination, and can also contain test messages. There can be only one report queue per computer.
- *Private system queues* are a series of private queues that store administrative and notification messages that the system needs to process messaging actions.

Most of the work you do in your applications will involve accessing public queues and their messages. However, you will most likely use several different kinds of the system queues in your day-to-day operations, depending on your application's need for journal recording, acknowledgement, and other special processing.

Synchronous and Asynchronous Communication

Queue communication is inherently *asynchronous* in that messages are sent to a queue and received from a queue in separate processes. In addition, you can perform receive operations asynchronously in that the person who wants to receive a message can call the **BeginReceive** method for any given queue and then immediately go on to other tasks without waiting for a reply. This is very different from what is known as *synchronous communication*.

In synchronous communication, the sender of a request must wait for a response from the intended receiver before performing other tasks. The amount of time that the sender must wait depends entirely on the amount of time it takes for the receiver to process the request and send a response.

> **Note** Synchronous or asynchronous retrieval of messages is a separate issue from sending messages. Messages are always sent asynchronously.

For more information on asynchronous processing in message queues, see Asynchronous Message Processing.

Message Security

You can help secure the content of messages that you send and receive in the following ways:

- You can use authentication to verify the source of messages your applications receive.
- You can use encryption to ensure that your messages cannot be read or used by unauthorized persons.
- You can use access control rights to restrict users with ACL-based security and code with code access security from sending messages to, or reading messages from, a particular queue on a computer.
- You can use auditing to record which users attempt to access Message Queuing objects, the type of operation attempted, and if that access succeeded or failed.

For more information, see Message Queue Security.

Installing Message Queuing

You must have Message Queuing installed on your development computer if you want to work with message queues either in code or in Server Explorer. You can find instructions on installing Message Queuing in your Windows 2000 or Windows NT documentation. When you install, you must specify whether you are creating a new primary Message Queuing server that will act as the hub of a new network, an independent client of an existing network, or a dependent client of an existing network. In most cases you will not create a new network, but will join the existing Message Queuing network for your company or workgroup.

Where to Go for Background Reading

The remaining topics in this section provide you with the information you need to use Message Queuing components in your applications. If you need more information on messaging technologies outside the context of Visual Studio or the .NET framework, there are many sources of information available to you in the MSDN library and on the Microsoft Web site:

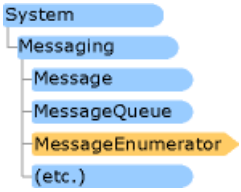
Creating Messaging Components

MessageQueue Programming Architecture

The **MessageQueue** component uses these portions of the Microsoft .NET Framework namespaces:



When you add an instance of the **MessageQueue** component to your Visual Studio project, the system automatically creates the references and import statements you need to access these namespaces and classes. However, if you are creating your **MessageQueue** components in code or in the .NET Framework SDK, you might need to create a reference to **System.Messaging** and add a statement to your project importing (in Visual Basic) or using (in C#) that namespace.

For instructions on adding and removing project references, see Adding and Removing References.

Key Programming Elements in the MessageQueue Base Class

You can use the following methods to interact with an instance of the **MessageQueue** component:

- Use the Create method to create a new message queue using the path you specify, and use the Delete method to delete an existing queue.
- Use the Exists method to see whether a particular message queue exists.
- Use the GetPublicQueues method to locate message queues in your Message Queuing network.
- Use the Peek or BeginPeek method to look at messages in a particular queue without removing the messages from the queue.
- Use the Receive and BeginReceive methods to retrieve the message at the front of the specified queue and remove it from the queue.
- Use the Send method to send a message to the specified queue.

You can view details about your Message Queuing installation by using Server Explorer to look at the messaging server. For more information, see Finding Queues in Server Explorer. You can also get detailed information about the configuration of your message queue network by using Message Queuing Explorer, which is installed automatically with Message Queuing.

> **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

Walkthrough: Creating a Queue and Working with Messages

The procedures in this topic demonstrate the process of creating a message queue using the **MessageQueue** component. Using that component, you send messages to the queue and retrieve messages from it. The messages log help requests.

> **Note** To see queue information in Server Explorer or to access queues programmatically, you must install the **Message Queuing Services** Windows component on your client computer. To add this service, use the **Add/Remove Programs** tool in the **Control Panel**.

> **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

To create a message queue on your computer

1. On the **File** menu, point to **New**, and then click **Project**.
2. In the **New Project** dialog box, choose Visual Basic or Visual C# in the left pane, then choose the **Windows Application** template. Name it **MessageQ**.
3. Open Server Explorer. For more information, see Accessing and Initializing Server Explorer .
4. Expand the **Servers** node.

   > **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

5. Expand the node for your local server. The node for your local server is identified by the computer name.
6. Expand the **Message Queues** node.
7. Right-click **Private Queues** and select **Create Queue** from the shortcut menu.
8. Enter **HelpRequest** for the queue name. Do not check **Make Transactional**.
9. A new private queue named **HelpRequest** is created and appears in Server Explorer.

   > **Note** You can also view the newly created queue through the **My Computer** icon. Right-click the **My Computer** icon on your desktop and select **Manage** from the shortcut menu. Expand the **Services and Applications** node. Expand the **Message Queuing** node and select the **Private Queues** folder. The new queue appears in the queue list.

To add a MessageQueue component for your message queue

1. Drag the **HelpRequest** queue from Server Explorer onto your form. A new **MessageQueue** component is added to the project, configured for the **HelpRequest** queue.

   The **MessageQueue** component is used to programmatically access the messages contained in the **HelpRequest** queue you created in the previous section.

2. Set the **Name** property of the **MessageQueue** component to **helpRequestQueue**.
3. In the Properties window, expand the **MessageReadPropertyFilter** node. Set the value of **Priority** to **true**. This causes the priority of the message to be retrieved when a message is retrieved from the queue.

The user interface that you create in the next procedure allows the user to enter some text for a help request and set the priority of the message. The user clicks a Send button to send the request to the queue. A datagrid displays the contents of the queue. The user interface also contains buttons to update the grid with the current contents of the queue and purge the queue.

To create the user interface

1. From the **Windows Forms** tab of the Toolbox, add the following controls to Form1:

   - Two labels
   - Two text boxes
   - Three buttons
   - One check box
   - One datagrid

2. Set the following properties of the controls:

Control	Property	New Value

Label1	Text	Name
Label2	Text	Message
TextBox1	Name	txtName
	Text	(blank)
TextBox2	Name	txtMessage
	Text	(blank)
	Multiline	true
Button1	Name	sendMessage
	Text	Send message
Button2	Name	refreshMessages
	Text	Refresh message list
Button3	Name	purgeMessages
	Text	Purge message list
CheckBox1	Name	highPriority
	Text	High priority
DataGrid1	Name	messageGrid

3. Arrange the controls in an orderly way.

To send a message to the queue

1. In the designer, double-click the **sendMessage** button to create the **Click** event handler in the Code Editor.
2. Add code to the method to create a new **Message** instance and send it to the queue, and to update the message display. You will write the `DisplayMessages` method in the next step.

```
' Visual Basic
Private Sub sendMessage_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles sendMessage.Click
   Dim theMessage As System.Messaging.Message = _
      New System.Messaging.Message(Me.txtMessage.Text)
   theMessage.Label = Me.txtName.Text
   If highPriority.Checked Then
      theMessage.Priority = Messaging.MessagePriority.Highest
   Else
      theMessage.Priority = Messaging.MessagePriority.Normal
   End If
   helpRequestQueue.Send(theMessage)
   DisplayMessages()
End Sub

// C#
private void sendMessage_Click(object sender, System.EventArgs e)
{
   System.Messaging.Message theMessage =
      new System.Messaging.Message(txtMessage.Text);
   theMessage.Label = txtName.Text;
   if (highPriority.Checked)
      theMessage.Priority = System.Messaging.MessagePriority.Highest;
   else
      theMessage.Priority = System.Messaging.MessagePriority.Normal;
   helpRequestQueue.Send(theMessage);
   DisplayMessages();
}
```

3. Add a method to display the contents of the queue in the **DataGrid** control. This method uses the **MessageQueue.GetAllMessages** method to retrieve all the messages from the queue. The selected queue properties are added to a **DataTable** object, which is used as the data source for the **DataGrid** control. To retrieve the text of the message, you need to create a formatter for the message.

```
' Visual Basic
Private Sub DisplayMessages()
   ' Create a DataTable
   Dim messageTable As New DataTable()
   messageTable.Columns.Add("Name")
   messageTable.Columns.Add("Message")
   messageTable.Columns.Add("Priority")
   Dim messages() As System.Messaging.Message
   messages = helpRequestQueue.GetAllMessages()
   ' Need a formatter to get the text of the message body.
   Dim stringFormatter As System.Messaging.XmlMessageFormatter = _
      New System.Messaging.XmlMessageFormatter(New String() _
      {"System.String"})
   Dim index As Integer
   Dim am As System.Messaging.Message
   ' Add each message to the DataTable
   For index = 0 To messages.Length - 1
      messages(index).Formatter = stringFormatter
      am = messages(index)
      messageTable.Rows.Add(New String() _
         {am.Label, am.Body.ToString(), am.Priority.ToString()})
   Next

   messageGrid.DataSource = messageTable
End Sub

// C#
private void DisplayMessages()
{
   DataTable messageTable = new DataTable();
   messageTable.Columns.Add("Name");
   messageTable.Columns.Add("Message");
   messageTable.Columns.Add("Priority");
   System.Messaging.Message[] messages;
   messages = helpRequestQueue.GetAllMessages();
   System.Messaging.XmlMessageFormatter stringFormatter;
   stringFormatter = new System.Messaging.XmlMessageFormatter(
      new string[] {"System.String"});
   for (int index = 0; index < messages.Length; index++)
   {
      messages[index].Formatter = stringFormatter;
      messageTable.Rows.Add(new string[] {
         messages[index].Label,
         messages[index].Body.ToString(),
         messages[index].Priority.ToString() });
   }
   messageGrid.DataSource = messageTable;
}
```

To display the contents of the queue

1. In the designer, double-click the **refreshMessage** button to create the **Click** event handler in the Code Editor.
2. Within the **Click** event handler, call the **DisplayMessages** method.

```
' Visual Basic
Private Sub refreshMessages_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles refreshMessages.Click
   DisplayMessages()
```

```
End Sub

// C#
private void refreshMessages_Click(object sender, System.EventArgs e)
{
   DisplayMessages();
}
```

To purge the contents of the queue

1. In the designer, double-click the **purgeMessage** button to create the **Click** event handler in the Code Editor.
2. Call the **Purge** method of the **helpRequestQueue**, and then refresh the contents of the **DataGrid** control.

```
' Visual Basic
Private Sub purgeMessages_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles purgeMessages.Click
   helpRequestQueue.Purge()
   DisplayMessages()
End Sub

// C#
private void purgeMessages_Click(object sender, System.EventArgs e)
{
   helpRequestQueue.Purge();
   DisplayMessages();
}
```

To test the application

1. Press F5 to run the application.
2. Enter your name and a short message.
3. Click **Send message** to send the message to the queue and update the display.
4. Click **Purge messages** to delete all the messages in the queue. The list of messages will be empty.

Finding Queues in Server Explorer

Using Server Explorer, you can explore existing queues on any computer to which you have access. You can view any public, private, or system queue available on these computers, including those queues you create in Visual Studio .NET.

> **Note** The Servers node of the Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

You can also see information about queues in the Windows 2000 Computer Management window, or in the Create Message Queue dialog box that appears when you set the path for an instance of the **MessageQueue** component.

To locate a queue in Server Explorer

1. Expand the **Server** node, and then expand the node for the server you want to view.

   > **Tip** If the server you want to view is not listed, you need to add it. For more information, see Accessing and Initializing Server Explorer.

2. Locate and expand the **Message Queues** node beneath it.

   > **Note** If the Message Queues node will not expand, an error icon appears next to it. This means that the computer on which you are trying to view queues does not have Message Queuing installed. For information on how to install and configure Message Queuing, see your Message Queuing documentation.

3. Expand **Public Queues**, **Private Queues**, or **System Queues** depending on the type of queue you are trying to locate.

   > **Note** Expanding a public message queue can take a while if the domain is large, or if the domain controller uses an older version of Message Queuing. Use Message Queuing version 2.0 or above for the best performance.

4. Expand the node for the queue you want to work with.

To find a queue in the Message Queuing node of Computer Management

1. On the desktop for your computer, right-click **My Computer**, and then click **Manage**.
2. In the dialog box that appears, expand the **Services and Applications** node.
3. Expand the **Message Queuing** node. A full list of the queues on the computer appears.

Creating, Deleting, and Administering Queues | Create Message Queue Dialog Box

Creating Queues

You create a queue to provide a resource with which your messaging components can interact. For example, suppose you are building an order entry system that places orders into queues as they are received from the sales force or from direct customer interaction on a Web site. You might begin by creating an OrderEntry queue on your Message Queuing enterprise. All of the components you create to process orders will interact with this queue.

There are two ways you can create a queue: by using Server Explorer window or by using the Create constructor from your code. You can use Server Explorer or the Windows 2000 Computer Management window to verify that your queue has been created successfully.

> **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

You can create a public queue on your own computer or any Message Queuing computer to which you have domain or enterprise administrative access rights. You can also create private queues on your local computer only. For more information on access rights, see Message Queue Security, or see "Access Control for Message Queuing" in the documentation for the Computer Management dialog box.

> **Note** It is important to note the difference between creating a queue and creating an instance of the **MessageQueue** component. When you use the Create constructor, you are creating a new queue in the Message Queuing network, rather than a component in your project or application. When you create an instance of the **MessageQueue** component, you create a component inside your project that references an existing queue in the operating system.

You can also configure an installation component to create or locate an existing queue when your application is deployed. For more information, see Custom Actions Management in Deployment.

To create a queue from Server Explorer

When you add an instance of the **MessageQueue** component to your Visual Studio project, the system automatically creates the references and import statements you need to access these namespaces and classes.

1. Open Server Explorer and access the server on which you want to create a queue. For more information, see Accessing and Initializing Server Explorer.
2. Right-click the **Message Queues** node.
3. Right-click either **Public Queues** or **Private Queues**, depending on the type of queue you want to create, and then click **Create Queue**.
4. In the **Create Message Queue** dialog box, type a name for your queue.
5. If you want to make the queue transactional, select **Make Queue Transactional**.

   > **Note** For more information, see Transactional Message Processing.

   > **Note** Creating a public message queue can take longer than expected if the domain is large and the domain has many domain controllers. This is because it takes time for the new public queue to replicate from your machine's domain controller to all other domain controllers in the domain. You may experience a delay during this replication process.

To create a public queue programmatically

1. Right-click on the project and select **Add Reference**. Add a reference to **System.Messaging.dll**.
2. Use the **Create** method to create a public queue on your computer. Your code should look like this:

```
' Visual Basic
System.Messaging.MessageQueue.Create("myMachine\MyQueue")

// C#
System.Messaging.MessageQueue.Create(@"myMachine\MyQueue");
```

> **Tip** You can use an overload of the **Create** method to indicate that you want to create a transactional queue. You can also use a period (.) in the path to indicate the local machine.

Security Note When you create a message queue, be aware that the resource may already exist. Another process, perhaps a malicious one, may have already created the resource and have access to it. When you put data in the message queue, the data is available to the other process. For information on existing queues, see Retrieving Queues.

To create a private queue programmatically

- Use the **Create** method, specifying the necessary syntax, **Private$**, in order to create a private queue on your computer. Your code should look like this:

```
' Visual Basic
System.Messaging.MessageQueue.Create(".\Private$\MyPrivateQueue")

// C#
System.Messaging.MessageQueue.Create(@".\Private$\MyPrivateQueue");
```

To verify that your message queue was created

You can use Server Explorer or the Windows 2000 Computer Management window to verify that your message queue was created.

- In Server Explorer, refresh the **Message Queues** node by right-clicking **Queues** and then clicking **Refresh**. It may take a moment for your queue to appear.

  – or –

- To see message-queuing information in Windows 2000, follow these steps:

  1. Right-click **My Computer** on the desktop, and then click **Manage**.
  2. In the dialog box that appears, expand the **Services and Applications** node, and then expand **Message Queuing**. You can find your queue and its messages in this node.

Creating, Deleting, and Administering Queues | Creating MessageQueue Component Instances

Queue Reference Recommendations

If you create an instance of the **MessageQueue** component, you need to indicate what queue you want the component to communicate with. There are three ways to refer to a queue in your code:

- By path — the path to a queue uniquely identifies the computer and queue name for the queue in which you are interested.
- By format name — a unique identifier for the queue that is generated by MSMQ when the queue is created or generated later by the application.
- By label — a descriptive and potentially non-unique name for the queue that is assigned by the queue administrator when the queue is created.

When you create a new queue, rather than a new instance of the **MessageQueue** component, you must use the path. Format name and label are assigned by the Message Queuing system after the queue is created. When you refer to an existing queue in code or from the Toolbox, however, you can choose which method of referencing you want to use. Whatever method you choose is stored in the component's **Path** property.

Using Path to Refer to a Queue

A queue path takes the form **servername\queuename**. Paths to a queue are always unique. The following table lists the path information used for each type of queue:

Queue Type	Syntax Used in Path
Public queue	MachineName\QueueName
Private queue	MachineName\Private$\QueueName
Journal queue	MachineName\QueueName\Journal$
Machine journal queue	MachineName\Journal$
Machine dead-letter queue	MachineName\Deadletter$
Machine transactional dead-letter queue	MachineName\XactDeadletter$

You can use `"."` for the local machine name, so that `"YourMachine\MyQueue"` is equivalent to `".\MyQueue"`.

The following are a few caveats about using a path to refer to your queues:

- When the domain controller on a Message Queuing server receives an operation for a queue that is referenced by path, it must resolve that path and determine the format name of the queue in question. This may result in slightly slower performance than if you refer to the queue by format name directly.
- If you are designing your component to be used as an XML Web service, you will get the best performance results by using the format name method of referring to queues rather than the path method.
- You cannot refer to a queue by path if you want to send messages to it when the queue is disconnected. Disconnected messages must be sent using the format name.

You can retrieve the path for a queue by querying and combining the return results of two separate properties in the MessageQueue base class — the MachineName property and the QueueName property.

In code, referencing a queue by path looks like this:

```
' Visual Basic
MessageQueue1.Path = "YourMachine\MyQueue"

// C#
MessageQueue1.Path= @"YourMachine\MyQueue";
```

> **Note** The @".\MyQueue" syntax for C# is equivalent to using ".\\MyQueue" instead. The @ sign indicates a literal string. For more information, see string.

Using Format Name to Refer to a Queue

Format names take the form of a string indicating whether a queue is public or private, followed by a generated GUID for the queue and other identifiers as necessary. The following table lists the path information used for each type of queue:

Queue Type	Syntax Used in Format Name
Public queue	FORMATNAME:PUBLIC=QueueGUID

Private queue	FORMATNAME:PRIVATE=MachineGUID\QueueNumber
Journal queue	FORMATNAME:PUBLIC=QueueGUID;JOURNAL – or – FORMATNAME:PRIVATE=MachineGUID\QueueNumber;JOURNAL

You do not assign a format name to a queue; instead, the queue manager generates this value when the queue is created. Referencing a queue by its format name is the most direct way to access a queue, because the domain controller on the server does not have to interpret the reference as it does when you refer to the queue by path.

The following are a few hints about referencing your queues by format name:

- If you intend to send messages to a disconnected queue, you must refer to the queue by format name rather than path, because the path will not be available to resolve with if the queue is offline.
- Be aware that format names may become invalid when your network topography changes or when a queue is deleted and re-created.

You can retrieve a format name for a queue by querying the FormatName property in the **MessageQueue** class.

In code, referencing a queue by format name looks like this:

```
' Visual Basic
MessageQueue1.Path = _
   "FORMATNAME:PUBLIC=3d3dc813-c555-4fd3-8ce0-79d5b45e0d75"

// C#
MessageQueue1.Path =
   "FORMATNAME:PUBLIC=3d3dc813-c555-4fd3-8ce0-79d5b45e0d75";
```

Using Labels to Refer to Queues

You can also refer to a queue by its label, which is a descriptive text label given to the queue by its administrator. Labels are not always unique, so you will receive an error if a name conflict exists when you try to connect to a specific queue using its label.

Labels can be useful in a situation where you know you are going to be moving a queue from one computer to another. If you refer to the queue by label only, all of your operations will continue to work successfully after the queue has been moved to its new location, provided that there are no other queues with that label on the new computer. If there are, the **Send** method will produce an error.

You can retrieve the label for a queue by querying the Label property in the **MessageQueue** class.

In code, referencing a queue by label name looks like this:

```
' Visual Basic
MessageQueue1.Path = "LABEL:MyQueue"

// C#
MessageQueue1.Path= "LABEL:MyQueue";
```

Creating, Deleting, and Administering Queues | Setting Queue References | Creating Queues | Creating MessageQueue Component Instances

Setting Queue References

You have three choices in the way you refer to a queue in your project — you can refer to it by the path to the queue, by the queue's automatically generated format name, or by the non-unique descriptive label of the queue. Each of these ways of referencing a queue has its advantages and disadvantages. For more information, see Queue Reference Recommendations.

> **Note** When you set a queue reference, you are merely linking the **MessageQueue** component you created to the existing queue. You are not changing the way the actual queue itself is identified on the server.

To set a queue reference

1. Create an instance of the **MessageQueue** component. For more information, see Creating MessageQueue Component Instances.
2. In the Properties window, select the **Ellipsis** button ( ) next to the **Path** property to display the **Message Queue Browser** dialog box.
3. In the dialog box, browse the **Select Message Queue** list and select the queue you want to reference.
4. In the **Reference Queue By** drop-down list, select one of the following:
   - To refer to the queue by its path, select **Path**.
   - To refer to the queue by its format name, select **FormatName**.
   - To refer to the queue by its label, select **Label**.
5. Click **OK** to return to the Properties window. The **Path** property now shows the path, format name, or label for the queue you selected.

Creating, Deleting, and Administering Queues | Queue Reference Recommendations

Deleting Queues

You can delete queues that exist on your local computer in two ways: from code or from Server Explorer. You can delete any public or private queues on your local computer, provided that you have the appropriate access rights. To delete a local queue, you must have either full control access rights assigned to you by the queue's owner, or explicit Message Queuing access rights to delete queue-related items from that machine. You cannot delete queues on other computers.

> **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

> **Note** You do not need to purge a queue's messages before deleting the queue. When you delete a queue, all of its messages are deleted with it. These messages are not sent to a dead-letter queue and cannot be retrieved. For more information on purging, see Purging Queue Contents.

To delete a message queue from Server Explorer

1. Open Server Explorer, and then expand the node for your server.
2. Expand the **Message Queues** node and locate the queue you want to delete.
3. Right-click the queue, and then click **Delete.**

> **Note** Deleting a public message queue can take longer than expected if the domain is large and the domain has many domain controllers. This is because it takes time for the deletion command to replicate from your machine's domain controller to all other domain controllers in the domain. You may experience a delay during this replication process.

To delete a message queue programmatically

- Use the Delete method to delete the queue you want. Your code should look something like this:

```
' Visual Basic
System.Messaging.MessageQueue.Delete("myMachine\MyQueue")

// C#
System.Messaging.MessageQueue.Delete (@"myMachine\MyQueue");
```

> **Note** This example shows the queue referenced by path. You can also refer to the queue you want to delete by format name or by label. For more information, see Queue Reference Recommendations.

Creating, Deleting, and Administering Queues | Queue Reference Recommendations | Purging Queue Contents

Purging Queue Contents

You can use the **Purge** method to clear the contents of any queue to which you have access rights in the Message Queuing system. For example, suppose you use a journal queue on your local Message Queuing client to record copies of all messages you send out. When that journal reaches its maximum size, you might use the Purge method to clear out the items you no longer need.

> **Note** Messages stored in journal and dead-letter queues count against the quota for the computer where the queue resides. When the quota is reached, these queues stop accepting new messages. It is important to periodically clear messages that are no longer needed from journal and dead-letter queues if you are using these in your application.

You must have Receive rights in Message Queuing to delete the contents of a queue. When you purge a queue, all of the messages it contains are discarded without being sent. You can purge a queue's contents from code or from Server Explorer.

To purge a queue's contents from Server Explorer

1. Open Server Explorer, and then expand the node for the server on which the queue you want to purge resides.

   > **Tip** If you do not see the server you want listed in the **Servers** node, right-click **Servers**, click **Add Server**, enter the name of your server, and then click **OK**.

   > **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

2. Expand the **Message Queues** node.
3. Expand the queue from which you want to delete messages. You will see one or more nodes for the queue's messages and its associated journal messages.
4. Right-click the message node you want to clear, and then click **Clear Messages**.

To purge a queue's contents programmatically

- Use the **Purge** method to clear the contents of the appropriate queue. Your code should look something like this:

```
' Visual Basic
Dim MessageQueue1 As New System.Messaging.MessageQueue()
MessageQueue1.Path = ".\MyQueue"
MessageQueue1.Purge()

// C#
System.Messaging.MessageQueue MessageQueue1 =
   new System.Messaging.MessageQueue();
MessageQueue1.Path = @".\MyQueue";
MessageQueue1.Purge();
```

Creating, Deleting, and Administering Queues | Creating Queues

Creating MessageQueue Component Instances

You create **MessageQueue** components when you want to build messaging functionality into your application. **MessageQueue** components allow you to connect to existing queues, send and receive messages, and otherwise add communication services to your application using a very small amount of code. For example, suppose you are building an order entry system that places orders into queues as they are received from the sales force or from direct customer interaction on a Web site. You might begin by adding an instance of the **MessageQueue** component to your project and configuring it to interact with an existing OrderEntry queue on your Message Queuing server.

You can add an instance of the **MessageQueue** component to Windows Forms, Web Forms, and component classes. **MessageQueue** components have no visual user interface. If you add an instance of the **MessageQueue** component to a visual designer (such as the Windows Forms Designer), the component appears in a small area below the bottom border of the form. This is known as the component tray and acts as a place to display all of the nonvisual items associated with the form.

> **Note** Nonvisual classes that inherit from **System.ComponentModel.Component** support a visual design surface similar to the component tray, on which your **MessageQueue** component and other components are arranged. The arrangement of items on this designer is not important, as the interface you see will never be displayed to the application's end users.

For instructions on how to configure **MessageQueue** components, see Message Queue Configuration Properties.

There are several ways you can create an instance of the **MessageQueue** component:

- You can drag an instance of the **MessageQueue** component from the Components Toolbox tab to a form or Component Designer.
- You can locate the queue you want in Server Explorer and add it to your designer, creating an instance of the **MessageQueue** component that is preconfigured to point to that queue.
- You can create an instance of the **MessageQueue** component in code.

To create an instance of the MessageQueue component from the Toolbox

1. Access the **Components** tab of the Toolbox.
2. Select the **MessageQueue** icon and drag it to the designer surface for your form or component.
3. Configure your component. For more information, see Message Queue Configuration Properties.

To create an instance of the MessageQueue component from Server Explorer

1. Open Server Explorer. For more information, see Accessing and Initializing Server Explorer.
2. Expand the **Servers** node and determine whether this node lists the server on which the queue you want resides.

   > **Tip** If the server you want to view is not listed, you need to add it. For more information, see Accessing and Initializing Server Explorer.

   > **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

3. Expand the node for the server you want to view, and then locate and expand the **Message Queues** node beneath it.

   > **Note** If the Message Queues node does not expand, the computer on which you are trying to view queues does not have Message Queuing installed. For information on how to install and configure Message Queuing, see your Windows 2000 or Windows NT Message Queuing documentation.

4. Locate the queue you want to add to your project, and then right-click it.
5. Click **Add to Designer**.
6. Configure your component. For more information, see Message Queue Configuration Properties.

To create an instance of the MessageQueue component programmatically

1. Create an instance of the **MessageQueue** class in code and set the Path property to determine which existing queue you want your component to reference. Your code might look like this:

```
' Visual Basic
Dim myMQ As New System.Messaging.MessageQueue()
```

```
myMQ.Path = ".\MyNewQueue"

// C#
System.Messaging.MessageQueue myMQ =
   new System.Messaging.MessageQueue();
myMQ.Path = @".\MyNewQueue";
```

Tip You can also do steps one and two in a single step, by using this format:

```
' Visual Basic
Dim myMQ2 As New System.Messaging.MessageQueue(".\MyNewQueue")

// C#
System.Messaging.MessageQueue myMQ2 =
   new System.Messaging.MessageQueue(@".\MyNewQueue");
```

Note You can refer to the queue by the path to the queue, the queue's automatically generated format name, or by the non-unique descriptive label of the queue. Each of these ways of referencing a queue has its advantages and disadvantages. For more information, see Queue Reference Recommendations.

2. Configure any other necessary properties for your queue. For more information, see Message Queue Configuration Properties.

See Also

Message Queue Configuration Properties | Accessing and Initializing Server Explorer

Message Queue Configuration Properties

There are a variety of properties you can manipulate on the queues and **MessageQueue** components you create. You can define these properties to help you set values that guide the queue's behavior, or query these properties to retrieve information about a queue with which your component interacts.

Properties That Reference a Queue

You use the **Path** property to determine what queue your component references. The path can be identified in one of three ways — by the physical path to the queue, by the queue's format name, or by the queue's descriptive label. For a full explanation of the differences between path, format name, and label, see Queue Reference Recommendations.

Queues can also be classified according to a category. You can use the **Category** property to determine the type of queue you are working with. **Category** is a GUID that is defined by the owner of the queue. You can either use a GUID-generation tool or make up your own number for the GUID. **Category** GUIDs do not have to be unique except within a single category. For example, you might define the same category for all of your order processing queues. This would allow you to retrieve all of them by that GUID.

Properties That Determine What Type of Data You Can Send

You use the **Formatter** property to determine how your message content will be serialized into a message before being sent to a queue, and how it will be extracted from a message after being received from a queue. Setting the **Formatter** property determines what type of content you can send in a message. For more information, see Message Serialization.

Properties That Control Interaction with a Queue

You can use the following properties to control how your component interacts with a queue:

- You can use the **DenySharedReceive** property to indicate that only one component at a time may look at the messages in a queue. This can be extremely useful in multi-user situations. When **DenySharedReceive** is set, the first component to peek at or receive messages off a queue is the only component that may perform these operations at that time. When the first component finishes its instance of that queue, it releases the queue either through garbage collection or by calling **Close**. For more information about garbage collection, see Reference Counting, Garbage Collection, and Object Lifetime.
- You can use the **CanRead** and **CanWrite** properties to determine if you have read and write access to a particular queue, or to set a queue to allow read and write access.
- You can use the **MaximumQueueSize** and **MaximumJournalSize** properties to determine the capacity, in kilobytes, of messages that a queue can receive. Once this maximum has been reached, messages are no longer accepted by the queue. By default, the maximum queue size defaults to the queue size set by the system administrator for Message Queuing. If no limit has been set, default queue size is infinite.
- You can use the **UseJournalQueue** property to determine whether copies of the messages retrieved from the queue are added to a journal queue.

For a full list of the properties associated with the **MessageQueue** class, see MessageQueue Members.

Sending and Serializing Messages

A message in Microsoft Windows Message Queuing consists of a body and a set of properties. Message bodies can contain text or any form of binary information, and can be encrypted. You set a message's body and properties programmatically, either by setting property values in the Properties window or by setting the required values in code. A message, including its body and all specified properties, cannot be bigger than 4 megabytes (MB) in size.

You can create and send messages with your **MessageQueue** components. Messages created in your applications can be sent to any public, private, journal, dead-letter, or transactional queue.

Sending Simple Messages

Using an instance of the **MessageQueue** component, you can send simple messages to a queue in as little as two lines of code. When you send a simple message, you must perform the following actions:

- Create a connection to the queue to which you want to send a message.
- Specify the appropriate formatter for the data you want to send. The formatter controls what type of data can be sent in a message and how that data is persisted. In simple cases, the default formatter is acceptable. For more information, see Message Serialization.
- Call the MessageQueue.Send method, passing the object to be sent.

Creating a Connection to the Queue

After you decide which queue you want to communicate with, you need to create an instance of the **MessageQueue** component that references the queue you want to use. You can create this component either from the Toolbox, from Server Explorer to your project, or by using the MessageQueue constructor.

To create a connection to the queue you want to communicate with

1. Create an instance of the **MessageQueue** component. For more information, see Creating MessageQueue Component Instances.
2. Use the component's Path property to connect to the queue with which you want to communicate by the queue path, format name, or label.

   Note If you created your component from Server Explorer, the **Path** property is set automatically to the queue path for that queue.

Providing the Data to Be Sent

Each **MessageQueue** component contains a series of default properties that are applied to all messages sent by that component, unless you specify otherwise in an individual message. In the simplest scenario, you can send a simple message to the queue using the default properties set for the component. For more information on these properties, see Default Message Properties.

You use the **Send** method to specify a message and send it to the queue. You can send objects, primitive data types, streams, and other kinds of data in a simple message.

The **MessageQueue** component takes the data you specify in the **Send** method's argument, persists it into a message, and sends the message to the specified queue.

Note You can also use the **Message** object to send far more complex messages to a queue. In addition, you can send messages as part of a transaction. For more information, see Sending Complex Messages.

To send a simple message

1. In the Properties window for your **MessageQueue** component, accept the default value for the Formatter property, or set the property to **XMLMessageFormatter** if you have changed the default value.
2. Use the **Send** method to send a simple message to your queue, specifying the message as an argument of the method.

   Your code to send a simple message might look like this:

```
' Visual Basic
' Create a connection to the queue.
Dim MessageQueue1 As New System.Messaging.MessageQueue (".\YourQueue")
' Send an integer.
MessageQueue1.Send(1)
' Send a string.
MessageQueue1.Send("Hello world")

// C#
// Create a connection to the queue.
System.Messaging.MessageQueue mq =
   new System.Messaging.MessageQueue (@".\YourQueue");
```

```
// Send an integer.
mq.Send(1);
// Send a string.
mq.Send("Hello world");
```

Sending Complex Messages

In addition to sending a simple message by specifying your message in the Send method's argument, you can gain more control over your messages by explicitly creating a **Message** object, rather than letting the shared **Send** method create and send one for you. By manipulating the properties of the resulting **Message** object, you can create more complex messages and exert more control over the way your messages are handled.

When you send a complex message, you must first create a connection to the queue with which you want to communicate, and then specify the data to send. However, as part of specifying the data to send, you will create an instance of the Message class, set the properties you need, and fine-tune the delivery mechanisms before sending your message. As with simple messages, the system persists your message object and sends it to the queue you specified.

For more information on the properties you can use to fine-tune your **Message** object, see Message Members.

> **Note** Using the **Message** object, you can send messages as part of a transaction. For more information, see Transactional Message Processing.

To send a complex message using the Message class

1. Create an instance of the **MessageQueue** component and set its Path property to the queue to which you want to refer. For more information, see Creating MessageQueue Component Instances.

   > **Note** If you created your component from Server Explorer, the **Path** property is set automatically to the queue path for that queue.

2. Create an instance of the **Message** object.
3. Set the body of the message and specify any properties you want to change from their default values.
4. Use the **Send** method to send your object to the queue.

   When you are finished, your code might look like this:

```
' Visual Basic
Dim myMQ1 As New System.Messaging.MessageQueue(".\YourQueue")
Dim newMessage As New System.Messaging.Message("Hello again")
newMessage.Label = "This is the label"
myMQ1.Send(newMessage)

// C#
System.Messaging.MessageQueue myMQ1 =
   new System.Messaging.MessageQueue (@".\YourQueue");
System.Messaging.Message newMessage =
   new System.Messaging.Message("Hello again");
newMessage.Label = "This is the label";
myMQ1.Send(newMessage);
```

Sending Messages to Disconnected Queues

There are two situations in which messages cannot readily be delivered to their queues: when the machine on which the queue resides is not available, or when the domain controller needed to route your message is not available. Message Queuing allows you to handle these situations so that if you are disconnected from the network or a necessary machine or controller is not available, you can continue to send messages. In these cases, the messages are temporarily stored on a queue on the local machine or a machine along the delivery route until the necessary resources are back online for delivery to be completed.

For example, suppose you have a central queue that records orders sent by your on-the-road sales force. The sales force works in disconnected mode much of the day, recording order information from customer sites, and dials in once a day to transfer all of this information to the central queue. Because messages can be sent to queues when the sender is disconnected, the sales force can send their messages immediately upon recording the customer's information, and the system caches those messages until the nightly call is placed.

Sending a message to a disconnected queue is almost identical to the process of sending a message to an available queue. You do not have to perform any special configuration in order for your component to store messages in a temporary queue when the queue to which you are sending is not available. There are two main differences to be aware of:

- If the queue is unavailable but the domain controller is working, you must identify the queue you want to send to by the queue's format name, rather than the path name. When a queue is disconnected, the domain controller for the queue cannot resolve the path name correctly. For more information on format names, see Queue Reference Recommendations.
- If you set a time-out interval on your message send operation, the time-out period will begin to count down as soon as the message is sent. This means that while the message sits on your local machine waiting for the queue to become available, the time-out period is active and the expiration time is approaching. If you want to use the time-out period, you must either set it to a large enough interval to allow for delivery or request negative acknowledgement for the message so you know if expiration has occurred. For more information on requesting acknowledgement when a message cannot be delivered, see Requesting Acknowledgement for Messages.

To send a message to a disconnected queue

1. Create an instance of the **MessageQueue** component. For more information, see Creating MessageQueue Component Instances.
2. Set the Path property for the component to the format name of the queue to which you want to send a message.

   > **Note** If you create the component from Server Explorer, this property will automatically refer to the path instead of the format name. To change to the format name, click the expansion icon next to the **Path** property. In the dialog box that appears, locate and select the queue your component references; then select **Format Name** in the **Reference Queue By** field and click **OK**.

3. Send your message normally.

   - For instructions on sending simple messages, see Sending Simple Messages.

     – or –

   - For instructions on sending messages using the **Message** object, see Sending Complex Messages.

See Also

Sending and Serializing Messages | Requesting Acknowledgement for Messages | Default Message Properties | Sending Simple Messages | Sending Complex Messages | Creating MessageQueue Component Instances | Verifying Messages at Design Time

Message Acknowledgement

You can set up your **MessageQueue** component to generate acknowledgement messages that tell you whether the message was successfully delivered. There are two main types of acknowledgement you can receive:

- Acknowledgement that the message reached its destination queue.
- Acknowledgement that the message was retrieved from the queue by the destination application.

Within each of these scenarios, you can also receive positive or negative acknowledgement. In *positive acknowledgement*, you receive an acknowledgement message when your message successfully reaches its destination queue or application. In *negative acknowledgement*, you receive an acknowledgement message when your message fails to reach its destination queue or application. A message might fail to reach its destination if its time-out period expires or if the message cannot be authenticated.

As with most operations in Message Queuing, acknowledgements are handled via sending a new message to a queue. In this case, the acknowledgement message is sent from the target queue to a special type of queue called an Administration queue. Acknowledgement messages differ from standard messages in that they contain no attached body; only the information in the message header is of interest in an acknowledgement.

> **Note** Acknowledgement messages for your application are sent to whatever queue you specify in the AdministrationQueue property, either in the DefaultPropertiestoSend class for your component instance or on the **Message** object. You determine the type of acknowledgement you want to receive by setting the AcknowledgeType property to one of its predetermined values.

You can check acknowledgement messages in the same way you check any message on a queue — by peeking at the acknowledgement queue or removing messages from it. For more information, see Reading and Receiving Messages.

For instructions on setting up acknowledgement, see Requesting Acknowledgement for Messages.

See Also

Sending and Serializing Messages | Requesting Acknowledgement for Messages | Reading and Receiving Messages

Requesting Acknowledgement for Messages

You can request positive acknowledgement, negative acknowledgement, or a combination of acknowledgement types on the messages sent by your **MessageQueue** components. For an overview of acknowledgement types, see Message Acknowledgement.

To request acknowledgement of a message

1. Create an instance of the **MessageQueue** component and set its Path property to the queue you want to reference. For more information, see Creating MessageQueue Component Instances.
2. Create the message you want to send. For more information, see Sending and Serializing Messages.
3. Set the AdministrationQueue property for your **Message** object to the queue to which you want acknowledgement messages sent.
4. Set the **Message** object's AcknowledgeType property in the **DefaultPropertiestoSend** area to the appropriate value:

   - If you want acknowledgement when a message reaches or fails to reach the queue to which it was sent, set the property to **FullReachQueue**.
   - If you want acknowledgement when the message reaches or fails to be retrieved from the queue before its time-to-be-received timer expires, set the property to **FullReceive**. Note that this acknowledgement is generated by the queue manager, rather than by the destination application.
   - If you want to request negative acknowledgment when a message fails to be retrieved from the queue, set the property to **NegativeReceive**.
   - If you want acknowledgement only if a message you send fails to reach the queue, set the property to **NotAcknowledgeReachQueue**.
   - If you want acknowledgement only if a message you sent could not be retrieved by its destination application, set the property to **NotAcknowledgeReceive**.
   - If you want positive acknowledgment when the message reaches its queue, set the property to **PositiveArrival**.
   - If you want positive acknowledgment when the message is successfully retrieved from the queue, set the property to **PositiveReceive**.

     Tip For information on positive and negative acknowledgment, see Message Acknowledgement.

5. Send the message, and then check the queue you specified in the **AdministrationQueue** property for the appropriate acknowledgement. For more information, see Reading and Receiving Messages.

To prevent acknowledgement messages from being sent

- Set the **AcknowledgeType** property for your component to **None**.

Message Queue Journal Storage

Journal queues allow you to save copies of messages as they are processed. You can store copies of the messages you send from your computer in the local machine journal queue, or you can store copies of messages removed from a queue in that queue's journal on the server.

Journal storage can be useful if you need to resend a message at a later point. For example, suppose you send a message to a queue and then receive negative acknowledgement that it could not be delivered. Acknowledgement messages do not contain the body of the original message; instead they give you some header information and a correlation ID that corresponds to the original message. If you have journal recording turned on, you can use this correlation ID to locate the original message in your machine's journal queue, re-create the message object, and resend it.

> **Note** You can use the ReceivebyCorrelationID or the PeekbyCorrelationID methods to retrieve a message by its correlation ID. Note that several messages may have the same correlation ID, and these methods will retrieve the first message in the queue with the given ID.

There are a few caveats you should note about journal queues:

- There is one global journal queue per machine. All messages sent from that machine will be recorded in that journal queue, whether they are delivered successfully or not. In addition, each queue has its own associated journal queue.
- There are two properties that control how journals are used. If you set the UseJournalQueue on the **MessageQueue** object, you enable journal storage for any messages received by that queue, not messages sent with that object. The messages sent with the queue will be placed in the queue journal. If you set the UseJournalQueue on the **Message** object, you enable system journal storage; this means that messages sent from your system will be placed in the sender's system queue.
- Journal queues have a maximum size, called a quota. This size is limited by the disk capacity of the computer on which the queue resides. After the queue capacity is reached, messages that would have been sent to the journal queue are no longer saved in the system. No errors are raised when this occurs. It is important that you periodically purge your journal queues to prevent this from occurring. For more information, see Purging Queue Contents.
- Journal queues are silent — that is, they cannot create acknowledgement messages of their own, send removed messages to dead-letter queues, or process time-outs.

For instructions on setting up journal storage for your messages, see Storing Messages in Journal Queues.

See Also

Sending and Serializing Messages | Storing Messages in Journal Queues | Purging Queue Contents

Storing Messages in Journal Queues

There are two ways you can set up the use of journal queues for sent messages — you can set a default property for your **MessageQueue** component so that all messages sent by it will use journals, or you can establish journal queue recording for individual messages you are sending.

For an overview of journal storage, see Message Queue Journal Storage.

To use journals for all messages sent by an instance of the MessageQueue component

1. Create an instance of the **MessageQueue** component and set its Path property to the queue to which you want to refer. For more information, see Creating MessageQueue Component Instances.
2. In the Properties window, set the UseJournalQueue property on the DefaultPropertiestoSend class for your component to **true**.

To set journal recording for an individual message

1. Create the message you want to send.
2. In code, set the **UseJournalQueue** property to **true**. Your code might look like this:

```
' Visual Basic
Message1.UseJournalQueue = True

// C#
Message1.UseJournalQueue = true;
```

To set journal recording for messages removed from a queue

1. Create an instance of the **MessageQueue** component and set its **Path** property to the queue to which you want to refer. For more information, see Creating MessageQueue Component Instances.
2. Set the **UseJournalQueue** property for the **MessageQueue** component that references that queue to **true**. Your code might look like this:

```
' Visual Basic
MessageQueue1.UseJournalQueue = True

// C#
MessageQueue1.UseJournalQueue = true;
```

To set the maximum size for a journal queue

1. Create an instance of the **MessageQueue** component and set its **Path** property to the journal queue you want to refer to. For more information, see Creating MessageQueue Component Instances.
2. Set the MaximumJournalSize property to the capacity, in kilobytes, that you want to use for your journal queue.

Sending and Serializing Messages | Message Queue Journal Storage | Purging Queue Contents | Default Message Properties | Requesting Acknowledgement for Messages | Creating MessageQueue Component Instances

Default Message Properties

When you create an instance of the **MessageQueue** component, you have the option of setting a series of default properties that messages sent by that component will use. This allows you to save time when defining your messages, and to have more control over the Send method without the need to create and configure **Message** objects.

> **Note** Only messages that are not sent using the **Message** object use the **DefaultPropertiestoSend** values. When you send a message using the **Message** object, the properties of the **Message** object are used.

You set default message properties by setting values in the **DefaultPropertiestoSend** section of the Properties window, or by setting values for the properties in the DefaultPropertiestoSend class. These default properties control features such as whether acknowledgement messages are generated and where they are sent, how your messages are encrypted and authenticated, and the time-out period for your messages.

This topic provides an overview of how you might set some of the more critical properties in this area. For a full description of the default properties, see DefaultPropertiesToSend Members.

Message Priority

Setting a default priority for your messages affects the order in which they are sent to their destination queues. You set the Priority property to determine the default priority for messages sent by your component. Priority ratings default to normal, with settings for lower and higher priorities.

The priority setting for a message determines where the message is placed in the queue. Messages sent with a higher priority are placed higher in the queue, and messages with a lower priority are placed lower in the queue. When the queue receives a set of messages with an identical priority setting, the messages are arranged in the queue according to the time when they were sent.

> **Note** You cannot set priority on messages that are being sent to transactional queues, because the order in which messages are processed on a transactional queues are determined by the transaction itself.

Acknowledgement and Response Properties

There are several default properties you can set that determine whether responses and acknowledgements will be generated for your component's messages and how these responses will be handled. The properties you can set as a default for all messaging operations include:

- The AcknowledgeType property and the AdministrationQueue properties, which you can use to determine whether acknowledgement messages should be generated when your messages reach or fail to reach their destination queue, or when the messages are retrieved from the queue by the target application. For more information, see Requesting Acknowledgement for Messages.
- The ResponseQueue property, which you can use to indicate the return path for any messages that will be sent by the application retrieving your messages from the queue. These messages differ from acknowledgement messages in that they are generated by the destination application, rather than by the queue manager.
- You can determine whether copies of your outgoing messages should be stored in a journal queue by setting the UseJournalQueue property and, similarly, whether undeliverable messages should be sent to a dead-letter queue by setting the UseDeadLetterQueue property.

Time-Out Properties

There are two time-related properties you can use to help maintain better control of your messages. Both of these determine how long a message can exist in the system before it is discarded. You use the TimeToReachQueue property to specify how long a message has to try to reach its destination queue. You use the TimeToBeReceived property to specify how long the message should remain in the system, from the time it is sent until the time it is removed from the queue by the destination application. If either timer interval expires, Message Queuing discards the message.

When a message is discarded due to an expired timer, the queue manager might take additional steps:

- If you set the **UseDeadLetterQueue** property to **true**, a copy of the discarded message will be sent to the specified dead-letter queue.
- If you set the **AcknowledgeType** property to send negative acknowledgements, an acknowledgement message will be sent to the specified Administration queue.

By default, no time-out interval is set for either property. If you set a value for both properties, the value in the

TimeToBeReceived property takes precedence.

Sending and Serializing Messages | Creating MessageQueue Component Instances

Message Serialization

Serialization is the process of taking objects and converting their state information into a form that can be stored or transported. The basic idea of serialization is that an object writes its current state, usually indicated by the value of its member variables, to persistent storage. Later, the object can be re-created by reading, or deserializing, the object's state from the storage. Serialization handles all the details of object pointers and circular object references that are used when you serialize an object.

In the message-queuing feature, serialization refers specifically to the process of converting an object or set of data into a message that can be sent to a queue, and then converting messages retrieved from the queue back into objects or data that your application can process.

A formatter object handles message serialization in your Visual Studio .NET or .NET framework applications. When a message is sent to the queue, the formatter serializes an object into a stream that can be sent to the message queue. When reading from a queue, the formatter deserializes the message data into the Body property.

You choose the appropriate type of formatter for the kind of data you want to send and receive. Visual Studio and the .NET Framework ship three predefined formatters, each designed to persist and de-persist a different type of data:

- The **XMLMessageFormatter** object persists objects and primitive data types into and out of messages using human-readable XML strings. This is the default formatter setting for **MessageQueue** components.
- The **BinaryMessageFormatter** object persists one or more connected objects into serialized streams. The result is very compact and fast to parse, but not human-readable.
- The **ActiveXMessageFormatter** object persists primitive data types, allowing for interoperability with components that use previous versions of Message Queuing. The resulting serialization is very compact. This formatter is designed with Windows in mind and does not produce human-readable results. However, it is an extremely fast method of serialization.

By default, an XMLMessageFormatter is created for you when you create a **MessageQueue** component instance and is associated with the instance. When the Send method is called on the **MessageQueue** instance, the body of your message is serialized using this formatter. You do not have to write any additional code to use the formatter during a send operation.

Reading a message is slightly more complex. To read from the queue using a formatter, you must set properties indicating how the body of the message should be handled. If you are using the **XMLMessageFormatter** object, you set the TargetTypes or TargetTypeNames property. If you are using the **BinaryMessageFormatter** object, you set a different series of properties. The **ActiveXMessageFormatter** object has no associated properties. For more information, see Reading and Receiving Messages.

In addition to using the formatters shipped with Visual Studio and the .NET framework, you can create your own formatters if you need to work with different types of data. You can import your formatter into a project and access it in code.

You choose the formatter you want to use by setting the **Formatter** property for the queue, message, or **MessageQueue** component with which you are working.

Advantages of XML Message Formatting

One advantage of the XML formatter is that you can read the strings that are created when the object or data is serialized. This means that if something happens and the message cannot be de-persisted from the message queue, you can take a look at the message itself and likely fix the problem.

Another advantage is that messages serialized with this formatter do not have to be deserialized by the same formatter object. That is, you do not need to have the same formatter class in the receiver as you had in the sender, as long as both parties know the data schema. In addition, messages serialized by the XML formatter do not necessarily have to be deserialized at all. Most browsers and other XML viewers can parse XML messages.

Verifying Messages at Design Time

You can use the Properties window to verify that your message-sending mechanism works correctly. Working with the Message Queues node in Server Explorer, you can select and expand queues to see the messages they contain, then select specific messages and view information about them in the Properties window. The Properties window displays information about the metadata attached to the message — its arrival time, authentication status, correlation ID, and so on — and also allows you to view the body of the message by accessing the BodyStream property.

To verify information about a message at design time

1. From design view, access Server Explorer. For more information, see Accessing and Initializing Server Explorer.

   > **Note** The Servers node of the Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

2. Expand the **Message Queues** node, and locate the queue you want to view information about under **Public Queues**, **Private Queues**, or **System Queues**.
3. Expand the queue you need and then locate the message you want under either **Journal Messages** or **Queue Messages**.
4. Click on a message.

   Information about that message appears in the Properties window.

5. To view the message body, click the **Ellipsis** button ( ) next to the **BodyStream** property.

   The Byte Array Property Editor dialog box appears.

6. Click on **Auto** to view the message's body in XML format, or choose one of the other view options as appropriate.

Reading and Receiving Messages

There are several ways you can read and receive messages from the queues in your system. First, you can either receive messages from the queue or you can peek at the messages on a queue without removing them. You can also create an event handler that will watch for a new message to arrive and automatically raise an event when the message arrives at the queue. The following topics explain each of these methods of working with queue messages.

Introduction to Reading and Retrieving Messages

There are several considerations to keep in mind when reading and retrieving messages.

Locking Access to a Queue

When you perform a receive operation, you may want to temporarily prevent other users from also removing messages from the queue with which you are working. You can do this by setting the DenySharedReceive property on that queue to **true**. Setting **DenySharedReceive** prevents any other users from removing messages from the same queue until you release your usage of it, either through garbage collection (For more information, see Reference Counting, Garbage Collection, and Object Lifetime) or by calling the Close method.

Properties to Retrieve

Messages have a large number of properties, and filtering the properties you want to receive can enable you to focus on only the information that is relevant to you. For example, if you are not working with transactional messages, you might not want to retrieve the properties associated with transactions. In this case, you would set the MessagePropertyFilter properties IsFirstInTransaction, IsLastInTransaction, TransactionID, and TransactionStatusQueue to **false**. Your **MessageQueue** component instance would not retrieve any of the property values corresponding to these properties whenever it gets a message from a queue. For more information, see Specifying Properties to Retrieve with a Message.

Specifying the Format for Received Messages

When you read messages from a queue, a formatter object is used to serialize and deserialize the message's contents as you manipulate the message. By default, an XMLMessageFormatter object is associated with any instance of the **MessageQueue** component you create, and you can use this to receive messages by setting a few necessary properties on it. You can also use various other types of formatter objects that are available to you; for more information on the formatters available, see Message Serialization.

The **XMLMessageFormatter** persists objects and primitive data types into and out of messages using human-readable XML strings. When you want to use this formatter to retrieve a message, you set a **TargetTypeNames** or **TargetTypes** property to indicate how the resulting message should be handled. For more information, see TargetTypeNames Property. If you are using another formatter object, the properties differ.

Specifying Properties to Retrieve with a Message

When you create an instance of the **MessageQueue** component, you can set a series of properties to indicate what properties you want to retrieve when the component gets a message from a queue. These properties exist in a class called MessagePropertyFilter Class and correspond to actual properties on the Message class. When you set the value for one of these properties to **true**, the component will retrieve the corresponding property each time a message is removed from the queue.

> **Tip** If you do not need access to some properties in your retrieved message and want to improve performance, you can set the **MessagePropertyFilter** to false.

For a full list of all of the properties you can set, see MessagePropertyFilter Class. By default, the properties retrieved with a message include properties indicating the time it was sent and arrived, several identifiers for the message, the message's label, the response queue, and the body of the message.

To specify the properties to retrieve with a message

1. Create an instance of the **MessageQueue** component and set its Path property to the queue to which you want to refer. For more information, see Creating MessageQueue Component Instances.
2. In the Properties window, expand the **MessageReadPropertyFilter** node.
3. Set the value for the properties you want to receive to **true**.

> **Note** You can set these in code, as well. When doing so, you can use the SetAll method to set all the filter properties to **true**, or the ClearAll method to set all the filter properties to **false**.

Specifying the Formatter for Retrieved Messages

You must indicate the formatter object you want to use to retrieve a message from a queue. A formatter indicates how a message will be deserialized when it is removed from the queue. Depending on the type of formatter you use, you might need to set additional properties to specify how the formatter should proceed.

By default, you use the **XMLMessageFormatter** for most operations. For more information on the formatters available to you, see Message Serialization. For information on the properties unique to the **XMLMessageFormatter** object, see Introduction to Reading and Retrieving Messages.

You can specify the formatter in code or in the Properties window. In addition, you can either set the formatter on the queue or on the message. You set the formatter on the queue when you plan to access the queue's messages directly, as in the following code:

```
' Visual Basic
Console.WriteLine(CStr(MessageQueue1.Receive().Body))

// C#
Console.WriteLine(MessageQueue1.Receive().Body.ToString());
```

You set the formatter on the message when you plan to retrieve a queue's contents through the message object:

```
' Visual Basic
Message1 = MessageQueue1.Receive()

// C#
message1 = messageQueue1.Receive();
```

To specify the formatter in the Properties window

1. Create and configure your **MessageQueue** component instance. For more information, see Creating MessageQueue Component Instances.
2. In the designer, click on the **MessageQueue** instance, and then access the Properties window.
3. Set the **Formatter** property to the appropriate value.
4. If you chose either the XMLMessageFormatter object or the BinaryMessageFormatter object, expand the property and set the necessary subproperties to configure your formatter.

To specify the formatter programmatically

1. Create and configure your **MessageQueue** component instance. For more information, see Creating MessageQueue Component Instances.
2. In the Code Editor, create a formatter object of type XMLMessageFormatter, ActiveXMessageFormatter, or BinaryMessageFormatter.
3. Set any necessary properties for your formatter.
4. Retrieve your message.

For example, the following code shows how to create and configure a component that uses the **XMLMessageFormatter** object to retrieve a message from a public queue called MyQueue.

```
' Visual Basic
Dim mq As New System.Messaging.MessageQueue(".\MyQueue")
Dim formatter As System.Messaging.XmlMessageFormatter = _
   CType(mq.Formatter, System.Messaging.XmlMessageFormatter)
formatter.TargetTypeNames = New String() {"System.String"}
Dim m As System.Messaging.Message = mq.Receive(New TimeSpan(0, 0, 3))

// C#
System.Messaging.MessageQueue mq =
   new System.Messaging.MessageQueue(".\\MyQueue");
string[] types = { "System.String" };
((System.Messaging.XmlMessageFormatter)mq.Formatter).TargetTypeNames =
   types;
```

```
System.Messaging.Message m = mq.Receive(new TimeSpan(0,0,3));
```

Receiving Messages Programmatically | Introduction to Reading and Retrieving Messages

Receiving Messages Programmatically

You can use a synchronous method called Receive to look at the contents of a queue. When you call the **Receive** method on a queue, the system removes the first message from the queue and returns it to you. This message is no longer available to other components looking at the queue.

> **Note** You can also look at the first message on a queue without removing it from the queue. For more information, see Peeking at Messages. You can also receive messages asynchronously. For more information, see Receiving Messages Asynchronously.

If there are no messages available on the queue when you call the **Receive** method, the method will wait until a message arrives on the queue. You can specify a time-out period if you want the method to wait for only a specified interval. The time-out period is specified as a TimeSpan object.

When you read messages from a queue, a formatter object is used to serialize and deserialize the message's contents as you manipulate the message. For more information, see Introduction to Reading and Retrieving Messages.

There are several forms of the **Receive** method — the basic method with several overloads that allow you to specify things such as time-out periods, a method called MessageQueue.ReceiveById that allows you to retrieve a particular message by its identifier, and a method called ReceiveByCorrelationID that allows you to retrieve a message by correlation ID. For an explanation of correlation IDs, see Message Queue Journal Storage.

To receive a message programmatically

1. Create an instance of the **MessageQueue** component and set its Path property to the queue to which you want to refer. For more information, see Creating MessageQueue Component Instances.
2. Specify the formatter to use to retrieve your message. For more information, see Specifying the Formatter for Retrieved Messages.
3. Create an instance of the **Message** object to hold the retrieved message.
4. Call the **Receive** method to remove the message from the queue.

   > **Tip** To specify a time-out for the **Receive** method, use a TimeSpan object to specify the length of time that you want the method to wait.

   When you are finished, your code might look like this:

```
' Visual Basic
Dim mq As New System.Messaging.MessageQueue(".\MyQueue")
mq.Send("1", "1")
Dim m As System.Messaging.Message
m = mq.Receive(New TimeSpan(0, 0, 3))
m.Formatter = New _
   System.Messaging.XmlMessageFormatter(New String()
   {"System.String,mscorlib"})
Console.WriteLine(m.Body)

// C#
System.Messaging.MessageQueue mq =
   new System.Messaging.MessageQueue(".\\MyQueue");
mq.Send("1", "1");
System.Messaging.Message m = mq.Receive(new TimeSpan(0,0,3));
m.Formatter = new System.Messaging.XmlMessageFormatter(new string[]
   {"System.String,mscorlib"});
Console.WriteLine(m.Body);
```

Reading and Receiving Messages | Peeking at Messages | Receiving Messages Asynchronously | Creating MessageQueue Component Instances | Specifying the Formatter for Retrieved Messages

Peeking at Messages

You can use the Peek method to look at the first message on any queue without removing that message from the queue. This allows your component to get information from the queue without preventing other applications or components from retrieving messages they were intended to process.

> **Note** **Peek** allows you to see only the first message on the queue. Because that message is not removed from the queue when you peek at it, you cannot then peek at subsequent messages. If you want to see all of the messages in a queue without removing them from the queue, you can use the GetAllMessages method or the GetMessageEnumerator method. For more information, see Queue and Message Collections.

If there are no messages in the queue when you call the **Peek** method, the method waits until a message arrives. You can specify a time-out period if you want the method to wait only a specified period of time. The time-out period is specified as a TimeSpan object. Most commonly, the time-out period will be set to either zero, in which case it checks for a message and does not wait at all, or to the default infinite setting, which waits indefinitely. You would set this in code using the following syntax:

```
' Visual Basic
msg.TimeToBeReceived = System.Messaging.Message.InfiniteTimeout

// C#
msg.TimeToBeReceived = System.Messaging.Message.InfiniteTimeout;
```

You can also set this in the Properties window by setting the TimeToBeReceived property for **DefaultMessagestoSend** to Infinity.

> **Tip** When using dependent clients, be sure the clock on the client computer is synchronized with the clock on the server that is running Message Queuing. Otherwise, unpredictable behavior might result when sending a message whose **TimeToBeReceived** property is not **InfiniteTimeout**.

Peeking can be synchronous or asynchronous. For more information, see Receiving Messages Asynchronously.

To peek at messages synchronously

1. Create an instance of the **MessageQueue** component and set its Path property to the queue to which you want to refer. For more information, see Creating MessageQueue Component Instances.
2. Create an instance of the **Message** object to hold the data the **Peek** method copies from the queue.
3. Call the **Peek** method to get data about the first message on the queue. Optionally, to specify a time-out for the **Peek** method, enter the length of time (as a **TimeSpan** object) that you want the method to wait as an argument of the method.

   For example, the following code shows how you can use the **Peek** method to return and display information about the first message on a queue. This example assumes that you are working on a Windows Forms application that contains a label called Label1, and that you are working with a queue called MyQueue.

```
' Visual Basic
Public Sub LookFirstMessage()
   Dim NewQueue As New System.Messaging.MessageQueue(".\MyQueue")
   Dim FirstMessage As System.Messaging.Message
   FirstMessage = NewQueue.Peek
   Dim targetNames() As String = {"System.String,mscorlib"}
   FirstMessage.Formatter = _
      New System.Messaging.XmlMessageFormatter(targetNames)
   Dim label As String = CStr(FirstMessage.Label)
End Sub

// C#
public void LookFirstMessage()
{
   System.Messaging.MessageQueue newQueue =
      new System.Messaging.MessageQueue(".\\MyQueue");
   System.Messaging.Message firstMessage;
   string[] types = { "System.String,mscorlib" };
```

```
    firstMessage = newQueue.Peek();
    firstMessage.Formatter =
       new System.Messaging.XmlMessageFormatter(types);
    string label = firstMessage.Label.ToString();
 }
```

Asynchronous Message Processing

You can retrieve messages asynchronously if you want to retrieve messages without tying up your application's processing. In asynchronous message processing, the method that starts a task is returned immediately without waiting for a result. The application can continue to do what it was originally doing while the task is completed. When the task completes, the server can notify the application that the message was successfully processed.

There are two types of asynchronous messaging operations — receiving messages asynchronously and peeking at messages asynchronously. When you retrieve a message asynchronously, you use the BeginReceive method and the EndReceive method to mark the beginning and end of the operation. The actions that occur are as follows:

- The **BeginReceive** method returns immediately and raises an event called ReceiveCompleted when a message becomes available on the queue or if the message you are peeking at or receiving already exists.
- The **ReceiveCompleted** method returns an object of type IAsyncResult that contains information about the asynchronous operation.
- After the completed event is received, you call the **EndReceive** method to complete the operation. Within the end call, you might access the message or retrieve it by accessing the ReceiveCompletedEventArgs class.

You can access the **IAsyncResult** object throughout the lifetime of the operation, but typically you will not use it until **EndReceive** is called. However, if you start several asynchronous operations, you can place their **IAsyncResult** values in an array and specify whether to wait for all operations or any individual operation to complete. In this case, you use the AsyncWaitHandle property of the **IAsyncResult** object to identify completed operations.

Peek, like **Receive**, uses two methods called BeginPeek and EndPeek to bracket the beginning and end of the asynchronous operation. **BeginPeek** returns immediately and raises an event called PeekCompleted when a message becomes available. Like **ReceiveCompleted**, this event returns an **IAsyncResult** object you can manipulate for information about the operation.

In addition, both asynchronous receive and peek operations can use a time-out period to specify how long you want to wait for a message to become available. To do so, you use an overloaded form of either method to pass a TimeSpan object that indicates the time to wait. The **ReceiveCompleted** or **PeekCompleted** event is raised if the time-out period expires, but the IsCompleted property on the **IAsyncResult** object is set to false to indicate that a message was not dealt with.

For more information on asynchronous processing, see the following topics:

For	See
Step-by-step instructions on receiving a message asynchronously	Receiving Messages Asynchronously
An overview of the **BeginPeek** method and its members	MessageQueue.BeginPeek Method
An overview of the **BeginReceive** method and its members	MessageQueue.BeginReceive Method

Receiving Notification of Your Asynchronous Operation

There are two ways you can receive notification when your asynchronous receive or peek operation completes successfully:

- You can create an event handler that will handle the **ReceiveCompleted** or **PeekCompleted** events when they occur.
- You can use a callback to automatically watch for incoming messages and pass processing to your application when a message arrives.

When you use event notification, you create a method that handles your message processing and returns a notification when the processing completes. You then call the method that begins the asynchronous processing. The system creates the event handlers for you automatically when you double-click your **MessageQueue** component in the designer.

> **Note** In the event-notification scenario, **BeginPeek** or **BeginReceive** returns a single message and then stops processing. You must call **BeginPeek** or **BeginReceive** again for each message you want to retrieve.

An alternate way to process messages asynchronously is to use a callback. A callback identifies a delegate you want to associate with your **BeginPeek** or **BeginReceive** operations. In this scenario, the delegate continues to watch for new event notification after each message is processed.

See Also

Receiving Messages Asynchronously | Reading and Receiving Messages | Peeking at Messages | Receiving Messages Programmatically

Receiving Messages Asynchronously

You can retrieve messages asynchronously in two ways: by using an event handler to receive notification when the operation finishes processing, or by using a callback. For an overview of asynchronous messaging, see Asynchronous Message Processing.

In event notification, you first bind an event handler to the procedure you want to run when the asynchronous call completes. You then call the BeginReceive method in your code. This starts the asynchronous processing and returns processing to your component when a message becomes available or when the time-out parameter expires. When the call returns, the system runs the delegate you have defined and processes the results of the retrieval. You then call the EndReceive method to indicate the end of the operation.

> **Note** **BeginReceive** will retrieve only a single message. If you want to continue processing messages asynchronously, you must either call the **BeginReceive** method again or use the callback parameter on **BeginReceive** to call a delegate that will continue to watch for new messages arriving on the queue.

In addition to receiving messages asynchronously, you can peek at messages asynchronously. The pattern for both processes is very similar, except that to peek asynchronously, you use the BeginPeek method.

To create the MessageQueue object programmatically

1. Add a reference to System.Messaging.dll to your project.
2. Create an instance of the **MessageQueue** object in the class you are implementing, and set its Path property (in the constructor) and the Formatter property.

```
' Visual Basic
' Add this to the class declarations.
Dim WithEvents mq As New System.Messaging.MessageQueue(".\MyQueue")
' Add this to the constructor
Dim targetTypeNames() As String = _
   New String() {"System.String,mscorlib"}
mq.Formatter = _
   New System.Messaging.XmlMessageFormatter(targetTypeNames)

// C#
// Add this to the class declarations.
System.Messaging.MessageQueue mq =
   new System.Messaging.MessageQueue(".\\MyQueue");
// Add this to the constructor.
mq.Formatter = new System.Messaging.XmlMessageFormatter(
   new string[]{"System.String,mscorlib"});
```

To create the MessageQueue object in the Designer

1. Add a reference to System.Messaging.dll to your project.
2. From the Toolbox, drag a **MessageQueue** component onto the Designer. Set the **Name** property to **mq**. Set the **Formatter** property to **XmlMessageFormatter**. Set the **Path** property to **".\MyQueue"**.

To receive a message asynchronously using event notification

1. Create an event handler for the ReceiveCompleted event. In the designer, double-click the **MessageQueue** component, and add the code shown below.

```
' Visual Basic
Private Sub mq_ReceiveCompleted(ByVal sender As System.Object, _
ByVal e As System.Messaging.ReceiveCompletedEventArgs) _
Handles mq.ReceiveCompleted
   ' Add code here to respond to message.
End Sub

// C#
```

```
private void mq_ReceiveCompleted(object sender,
System.Messaging.ReceiveCompletedEventArgs e)
{
   // Add code here to respond to message.
}
```

2. Write code within the event handler to retrieve the message, using the **Message** object to retrieve the results of the asynchronous call. The following code retrieves the message and displays it on the console.

```
' Visual Basic
Private Sub mq_ReceiveCompleted(ByVal sender As System.Object, _
ByVal e As System.Messaging.ReceiveCompletedEventArgs) _
Handles mq.ReceiveCompleted
   Dim m As System.Messaging.Message = mq.EndReceive(e.AsyncResult)
   m.Formatter = New System.Messaging.XmlMessageFormatter( _
      New String() {"System.String,mscorlib"})
   Console.WriteLine("Message: " + m.Body.ToString())
End Sub

// C#
private void mq_ReceiveCompleted(object sender,
System.Messaging.ReceiveCompletedEventArgs e)
{
   System.Messaging.Message m = mq.EndReceive(e.AsyncResult);
   m.Formatter = new System.Messaging.XmlMessageFormatter(
      new string[]{"System.String,mscorlib"});
   Console.WriteLine("Message: " + (string)m.Body);
}
```

3. Call the **BeginReceive** method somewhere in your code to start the asynchronous operation. For example, the following code calls the method when the user clicks a button.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles Button1.Click
   mq.BeginReceive()
End Sub

// C#
private void button1_Click(object sender, System.EventArgs e)
{
   mq.BeginReceive();
}
```

4. If you want to continue receiving messages asynchronously, call the **BeginReceive** method again in the **ReceiveCompleted** event handler, shown below. This makes your component continue processing new messages as they are received on the queue.

```
' Visual Basic
Private Sub mq_ReceiveCompleted(ByVal sender As System.Object, _
ByVal e As System.Messaging.ReceiveCompletedEventArgs) _
Handles mq.ReceiveCompleted
   Dim m As System.Messaging.Message = mq.EndReceive(e.AsyncResult)
   m.Formatter = New System.Messaging.XmlMessageFormatter( _
      New String() {"System.String,mscorlib"})
      Console.WriteLine("Message: " + m.Body.ToString())
   mq.BeginReceive()
End Sub
```

```
// C#
private void mq_ReceiveCompleted(object sender,
System.Messaging.ReceiveCompletedEventArgs e)
{
   System.Messaging.Message m = mq.EndReceive(e.AsyncResult);
   m.Formatter = new System.Messaging.XmlMessageFormatter(
      new string[]{"System.String,mscorlib"});
   Console.WriteLine("Message: " + (string)m.Body);
   mq.BeginReceive();
}
```

To receive a message asynchronously using a callback

1. Create a class that defines information relevant to the message task. In this case, define a `Customer` class.

```
' Visual Basic
Public Class Customer
    Public Name As String = ""
    Public Sub New(ByVal newName As String)
        Name = newName
    End Sub
End Class

// C#
public class Customer
{
    public string Name = "";
    public Customer(string name)
    {
        Name = name;
    }
}
```

2. Create an instance of the class. This object will be passed to the callback method.

```
' Visual Basic
Dim george As New Customer("George")

// C#
Customer george = new Customer("George");
```

3. Create a callback method according to the AsyncCallback delegate. This method will contain the processing to be done after the message is received. The IAsyncResult.AsyncState property of the **result** parameter will contain the object you created to pass information about the message task. In this case, the **AsyncState** is a `Customer` object.

```
' Visual Basic
Private Sub ReceiveCallback(ByVal result As System.IAsyncResult)
    Dim buyer As Customer = CType(result.AsyncState, Customer)
    Dim buyerName As String = buyer.Name
End Sub

// C#
private void ReceiveCallback(System.IAsyncResult result)
{
    Customer buyer = (Customer)result.AsyncState;
    string buyerName = buyer.Name;
}
```

4. Call the MessageQueue.BeginReceive (TimeSpan, Object, AsyncCallback) method somewhere in your code to start the

asynchronous operation. For example, the following code calls the method when the user clicks a button. A message is sent to the message queue and then read from the queue. The **ReceiveCallback** method, defined in step 3 above, is called when the message is received.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) _
    Handles Button1.Click
    MessageQueue1.Send("Buy six eggs.", george.Name)
    MessageQueue1.BeginReceive(New System.TimeSpan(0, 0, 5), george, _
        AddressOf ReceiveCallback)
End Sub

// C#
private void button1_Click(object sender, System.EventArgs e)
{
    messageQueue1.Send("Buy six eggs.", george.Name);
    messageQueue1.BeginReceive(new System.TimeSpan(0, 0, 5), george,
        new System.AsyncCallback(this.ReceiveCallback));
}
```

Transactional Message Processing

Transactional processing allows you to ensure that the messages in a transaction are delivered in order, are delivered only once, and are successfully retrieved from the destination queue. The **MessageQueue** component can be used to send and receive messages transactionally. When you send messages inside a transaction, you group a set of related messages. All the messages contained in the transaction are either delivered together in the order in which they were sent (a *committed* transaction), or automatically not sent or received if any problems occur (an *aborted* transaction).

There are two main types of transactions you can create from your applications:

- *Internal transactions* are used to send messages between two or more Message Queuing resources — that is, between two queues belonging to a Message Queuing enterprise.
- *External transactions* are used to send messages between queues and other resources, such as databases.

Internal and external transactions differ in their programming model, in the resource manager used to govern the transaction, and in their usage patterns.

Internal Transactions

Internal transactions are executed by creating an instance of the MessageQueueTransaction class and associating it with an instance of the **MessageQueue** component. An internal transaction is the simplest type of transaction. Messages are sent between one or more message queues, and Message Queuing's transaction coordinator governs the actions that occur. Because you control these steps in the process manually, internal transactions can be thought of as manual or explicit transactions, whereas external transactions are automatic or implicit.

The programming model for internal transactions are very simple — you call the Begin method of the **MessageQueueTransaction** class and pass an instance of this class to the sending or receiving method. You then call Commit to save the transaction's changes to the destination queue. For more information, see Sending Messages Within Internal Transactions.

Internal transactions are somewhat limited in functionality, in that you cannot perform transactions with non-message queuing resources such as databases. If you want to interact with a database in a transaction, you must use external transactions. However, in spite of these limitations, internal transactions have better performance than external transactions.

Both internal and external transactions require that you send the messages to a queue that has been marked as transactional. For more information, see Creating Transactional Queues.

External Transactions

External transactions are typically used when you want to send messages between queues and another type of resource. For example, you might want to retrieve a message from a queue and send it to a database, or vice versa. External transactions differ from internal transactions in several ways:

- External transactions rely on a coordinator that is not part of the Message Queuing system. In most cases, this will be the Microsoft Distributed Transaction Coordinator (DTC). The DTC enlists the necessary resources in the transaction and governs the process of determining whether all of the actions in the transaction succeed or fail as a unit.
- An external transaction has a more complex programming model. Instead of simply calling **Begin**, **Commit**, and **Abort**, you specify attributes that indicate an external transaction and register the component with COM+ 1.0 Services. You also must use a special form of the Send and Receive methods that takes a parameter for the type of transaction, and set this field to Automatic.

There are also other types of transactions that can be sent without using the **MessageQueue** component. For more information on transactions in Visual Studio .NET or the .NET Framework, see the following topics:

Reading and Receiving Messages | Creating Transactional Queues | Sending Messages Within Internal Transactions | Walkthrough: Creating a Message Queue Transaction with COM+ Services

Creating Transactional Queues

A transactional queue is created for the specific purpose of receiving and processing messages that are sent as part of a transactional activity. Nontransactional queues are unable to process messages that have been included in a transactional activity.

To send messages as part of a transactional activity, the receiving queue must be set to process transactions. This can be done programmatically by setting its Transactional property to **true**.

To create a transactional queue

1. Add a reference to the **System.Messaging.dll**. For more information, see Adding and Removing References.
2. Use the overloaded Create constructor to create a public, transactional queue, setting the second parameter to **true** to indicate that the queue should be transactional.

```
' Visual Basic
Dim mq2 As New System.Messaging.MessageQueue
mq2 = System.Messaging.MessageQueue.Create(".\MyTransQueue", True)

// C#
System.Messaging.MessageQueue mq2 =
   new System.Messaging.MessageQueue();
mq2 = System.Messaging.MessageQueue.Create(".\\MyTransQueue",true);
```

Note This syntax creates a public transactional queue. The exact syntax you use in the first parameter depends on the kind of queue you are trying to create. For more information, see Queue Reference Recommendations.

Reading and Receiving Messages | Transactional Message Processing | Sending Messages Within Internal Transactions | Creating Queues | Adding and Removing References | Queue Reference Recommendations | Walkthrough: Creating a Message Queue Transaction with COM+ Services

Sending Messages Within Internal Transactions

Internal transactions involve only Message Queuing resources and are managed entirely from within Message Queuing with the MessageQueueTransaction Class. You instantiate an instance of **MessageQueueTransaction** to handle the transaction process and pass it to the message you are choosing to send as a transaction.

The following methods control the transactional process:

Method	Used to
Begin	Indicate the start of a transaction that consists of one or more messages and operations.
Commit	Used to commit the transaction if all of the message operations it contained were performed successfully.
Abort	Used during error-checking to roll back a transaction.

Note A disconnected or full queue is not considered a failure.

In most cases, your transactional code should be enclosed within a Try...Catch statement. This allows you to specify the transaction in the **Try** portion of the statement, and then use the **Catch** statement to issue the **Abort** if any errors occur. See the code below for an example of this pattern.

To send messages within an internal transaction

1. Create an instance of the **MessageQueue** component and set its Path property to the queue to which you want to refer. For more information, see Creating MessageQueue Component Instances.
2. Create an instance of the MessageQueueTransaction class to control the transaction.
3. Call the **Begin** method of the **MessageQueueTransaction** class.
4. Define each message you want to send after calling **Begin**. For more information, see Creating MessageQueue Component Instances.
5. After the last message is sent, call **Commit** on the **MessageQueueTransaction** instance to close the transaction.
6. Enclose the entire transaction in **Try...Catch** error-checking code to handle any errors that arise.
7. If you detect an error, roll back the transaction by calling the **Abort** method.

   Your code might look like this:

```
' Visual Basic
Dim transaction As New System.Messaging.MessageQueueTransaction
Try
    transaction.Begin()
    MessageQueue1.Send("Message1", "Label1", transaction)
    MessageQueue1.Send("Message2", "Label2", transaction)
    MessageQueue1.Send("Message3", "Label3", transaction)
    transaction.Commit()
Catch
    transaction.Abort()
End Try

// C#
System.Messaging.MessageQueueTransaction transaction =
    new System.Messaging.MessageQueueTransaction();
try
{
    transaction.Begin();
    messageQueue1.Send("Message1", "Label1", transaction);
    messageQueue1.Send("Message2", "Label2", transaction);
    messageQueue1.Send("Message3", "Label3", transaction);
    transaction.Commit();
}
catch
{
    transaction.Abort();
}
```

Walkthrough: Creating a Message Queue Transaction with COM+ Services

This walkthrough creates a transaction supported by COM+ Services by using the **ServicedComponent** class. The walkthrough creates two transactional queues and moves data between them in a transaction hosted by Enterprise Services (COM+ Services). For an overview of Enterprise Services see Writing Serviced Components.

> **Note** You must install the Message Queuing components of your operating system to complete this walkthrough.

The first step in using a COM+ transaction service is to create a class that derives from the **ServicedComponent** class, found in the System.EnterpriseServices namespace. The **ServicedComponent** class is the base class used to create components that are hosted by COM+.

To create the ServicedComponent Class

1. Create a class library project. Name it TransactionComponent.
2. Add references to System.Messaging.dll and System.EnterpriseServices.
3. Replace Class1 with the class below.

   - The TransactionAttribute on the class directs the Distributed Transaction Coordinator to create a context for the object.
   - Classes derived from **ServicedComponent** must have a public default (parameterless) constructor.
   - Fields are added for the source and destination queues. These are exposed as properties, because the constructor cannot take parameters.
   - The AutoComplete attribute on the **Move** method indicates that at the end of the method, the component's vote towards the transaction is based on failure or success of this method. The method fails if an exception is thrown. If the method succeeds, the ContextUtil.SetComplete Method is called. For more information, see AutoCompleteAttribute Class and Voting in an Automatic Transaction.

```
' Visual Basic
<System.EnterpriseServices.TransactionAttribute( _
System.EnterpriseServices.TransactionOption.Required)> _
Public Class MessageMover
    Inherits System.EnterpriseServices.ServicedComponent

    Private sourceQueue As System.Messaging.MessageQueue
    Private destinationQueue As System.Messaging.MessageQueue

    Public Sub New()
    End Sub

    Public Property Source() As System.Messaging.MessageQueue
        Get
            Return sourceQueue
        End Get
        Set(ByVal Value As System.Messaging.MessageQueue)
            sourceQueue = Value
        End Set
    End Property

    Public Property Destination() As System.Messaging.MessageQueue
        Get
            Return destinationQueue
        End Get
        Set(ByVal Value As System.Messaging.MessageQueue)
            destinationQueue = Value
        End Set
    End Property

    <System.EnterpriseServices.AutoComplete()> _
```

```
    Public Sub Move()
        Dim sourceMessage As System.Messaging.Message
        sourceMessage = sourceQueue.Receive( _
            System.Messaging.MessageQueueTransactionType.Automatic)
        destinationQueue.Send(sourceMessage, _
            System.Messaging.MessageQueueTransactionType.Automatic)
    End Sub
End Class

// C#
[System.EnterpriseServices.TransactionAttribute(
System.EnterpriseServices.TransactionOption.Required)]
public class MessageMover : System.EnterpriseServices.ServicedComponent
{
   private System.Messaging.MessageQueue sourceQueue;
   private System.Messaging.MessageQueue destinationQueue;
   public MessageMover()
   {
   }

   public System.Messaging.MessageQueue Source
   {
      get
      {
         return sourceQueue;
      }
      set
      {
         sourceQueue = value;
      }
   }
   public System.Messaging.MessageQueue Destination
   {
      get
      {
         return destinationQueue;
      }
      set
      {
         destinationQueue = value;
      }
   }
   [System.EnterpriseServices.AutoComplete()]
   public void Move()
   {
      System.Messaging.Message sourceMessage;
      sourceMessage = sourceQueue.Receive(
         System.Messaging.MessageQueueTransactionType.Automatic);
      destinationQueue.Send(sourceMessage,
         System.Messaging.MessageQueueTransactionType.Automatic);
   }
}
```

To be hosted by COM+, components must have a strong name. The following procedure describes how to create a key file and use it to apply a strong name to the class library.

To give the class a strong name

1. Locate the Strong Name Tool (Sn.exe) and run it to create a key file, key.snk, in the project directory. The command looks

something like this:

```
sn -k ProjectDirectory\key.snk
```

2. In Solution Explorer, double-click AssemblyInfo.vb or AssemblyInfo.cs, depending on the language you are using. Add or replace the attributes for AssemblyDelaySign, AssemblyKeyFile, and AssemblyKeyName. The file location for the key file is given relative to the build location. You will need to confirm that the path is correct for your project configuration. For more information on the interaction of these three attributes, see Global Attributes.

```
' Visual Basic
<Assembly: AssemblyDelaySign(False)>
<Assembly: AssemblyKeyFile("..\..\key.snk")>
<Assembly: AssemblyKeyName("")>
// C#
[assembly: AssemblyDelaySign(false)]
[assembly: AssemblyKeyFile("..\\..\\key.snk")]
[assembly: AssemblyKeyName("")]
```

3. Build the application to create the DLL.
4. Now that the assembly has a strong name, it can be registered with COM+. The .NET Framework includes a tool for registering serviced components.

To register the component with COM+

1. Locate the .NET Services Installation Tool (Regsvcs.exe), located in the .NET Framework installation folder. The .NET Framework is installed in the operating system folder, not in the **Program Files** folder.
2. Run the tool to register TransactionComponent.dll. The command looks something like this:

```
regsvcs c:\DllPath\TransactionComponent.dll
```

> **Note** The registration tool may report that "The class TransactionComponent.MessageMover has no class interface, which means that unmanaged late bound calls cannot take advantage of AutoComplete methods." The message is a warning that because the component does not implement an interface, you will not be able to use the component in a late-bound call, such as if you were using VBScript. The component will work in this walkthrough.

You can use the Component Services tool to see the COM+ component you created.

To verify the results with Component Services

1. Open Control Panel.
2. Double-click the **Administrative Tools** icon.
3. Open **Component Services**.
4. Double-click the Component Services node under the Console Root to expand it.
5. Expand the **Computers** node.
6. Expand the **My Computer** node.
7. Expand the **COM+ Applications** node.
8. Find the TransactionComponent entry. Its presence verifies that the component is registered with Component Services. When you create an instance of TransactionComponent, it will be hosted in a COM+ Services context. The code executed (the **ProcessOrder** method) will run in the managed space, but the context (which tracks the success or failure of the transaction) will be maintained by COM+ Services.

The client application will be a Windows Form with code that is able to create and delete a message queue. The application will include two methods that use the COM+ transaction. The first will be a successful transaction. The second will be coded so that the transaction fails. This will allow you to experiment with the exception-handling features of COM+.

To create the client application

1. Add a new Windows Application project to the solution. Name it MessageMoverClient.
2. Add a reference to the TransactionComponent project. To use the .NET serviced component, you add a reference to the DLL

and instantiate the class.

3. Add references to System.Messaging.dll and System.EnterpriseServices.
4. Add a button to the form. Name the button **moveSucceeds** and set the Text property to **Succeed**. This button will execute code that successfully moves a new message from one queue to another in a complete transaction.
5. Create the Click event handler for the **moveSucceeds** button and add the code below to the method.

> **Note** This code creates and deletes message queues named SourceQueue and DestinationQueue. If these queues already exist on your computer, they may be deleted in the course of this walkthrough. Use the Computer Management application in the Control Panel item named **Administrative Tools** to look for these queues. See Step 7 below, for information on using the Computer Management application to examine message queues.

```
' Visual Basic
Dim mover As New TransactionComponent.MessageMover
Dim sourcePath As String = ".\SourceQueue"
Dim destinationPath As String = ".\DestinationQueue"

If System.Messaging.MessageQueue.Exists(sourcePath) Then
    Dim queue As New System.Messaging.MessageQueue(sourcePath)
    If (Not queue.Transactional) Then
        System.Messaging.MessageQueue.Delete(sourcePath)
        System.Messaging.MessageQueue.Create(sourcePath, True)
    End If
Else
    System.Messaging.MessageQueue.Create(sourcePath, True)
End If

If System.Messaging.MessageQueue.Exists(destinationPath) Then
    Dim queue As New System.Messaging.MessageQueue(destinationPath)
    If (Not queue.Transactional) Then
        System.Messaging.MessageQueue.Delete(destinationPath)
        System.Messaging.MessageQueue.Create(destinationPath, True)
    End If

Else
    System.Messaging.MessageQueue.Create(destinationPath, True)
End If

mover.Source = New System.Messaging.MessageQueue(sourcePath)
mover.Destination = New System.Messaging.MessageQueue(destinationPath)

mover.Source.Send("some message", System.Messaging.MessageQueueTransactionType.Single)
mover.Move()

MessageBox.Show("Move complete.")

// C#
TransactionComponent.MessageMover mover;
mover = new TransactionComponent.MessageMover();
string sourcePath = ".\\SourceQueue";
string destinationPath = ".\\DestinationQueue";

if (System.Messaging.MessageQueue.Exists(sourcePath))
{
   System.Messaging.MessageQueue queue = new System.Messaging.MessageQueue(sourcePath);
   if (!queue.Transactional)
   {
      System.Messaging.MessageQueue.Delete(sourcePath);
      System.Messaging.MessageQueue.Create(sourcePath, true);
```

```
    }
}
else
{
    System.Messaging.MessageQueue.Create(sourcePath, true);
}

if (System.Messaging.MessageQueue.Exists(destinationPath))
{
    System.Messaging.MessageQueue queue = new System.Messaging.MessageQueue(destinationPat
h);
    if (!queue.Transactional)
    {
        System.Messaging.MessageQueue.Delete(destinationPath);
        System.Messaging.MessageQueue.Create(destinationPath, true);
    }
}
else
{
    System.Messaging.MessageQueue.Create(destinationPath, true);
}

mover.Source = new System.Messaging.MessageQueue(sourcePath);
mover.Destination = new System.Messaging.MessageQueue(destinationPath);

mover.Source.Send("some message", System.Messaging.MessageQueueTransactionType.Single);
mover.Move();

MessageBox.Show("Move complete.");
```

6. In Solution Explorer, right-click the MessageMoverClient project and select "Set as Startup Project."
7. Run the application and click the **Succeed** button.

   Note If the computer is on a domain, there may be a delay between when the queue is created programmatically and when the queue is available to move messages. This delay may result in a failure of the **Move** method. You can add a call to the Thread.Sleep method to allow the queue to be created, or you can eliminate the code to create the queue and use Server Explorer to create the queue.

8. In the Control Panel item named **Administrative Tools**, open **Computer Management**. Expand the **Services and Applications** node and then the **Message Queuing** and **Public Queues** nodes. Locate the SourceQueue and DestinationQueue. Confirm that a new message was created and exists in DestinationQueue.
9. Add a button to the form. Name the button **moveFails** and set the Text property to **Fail**. This button will execute code that is not able to move a new message from one queue to another, because the destination queue does not exist.
10. Create the Click event handler for the **moveFails** button and add the code below to the method:

```
' Visual Basic
Try
    Dim mover As New TransactionComponent.MessageMover
    Dim sourcePath As String = ".\SourceQueue"
    Dim destinationPath As String = ".\DestinationQueue"

    If System.Messaging.MessageQueue.Exists(sourcePath) Then
        Dim queue As New System.Messaging.MessageQueue(sourcePath)
        If (Not queue.Transactional) Then
            System.Messaging.MessageQueue.Delete(sourcePath)
            System.Messaging.MessageQueue.Create(sourcePath, True)
        End If
    Else
        System.Messaging.MessageQueue.Create(sourcePath, True)
```

```
    End If

    If System.Messaging.MessageQueue.Exists(destinationPath) Then
        Dim queue As New System.Messaging.MessageQueue(destinationPath)
        If (Not queue.Transactional) Then
            System.Messaging.MessageQueue.Delete(destinationPath)
            System.Messaging.MessageQueue.Create(destinationPath, True)
        End If

    Else
        System.Messaging.MessageQueue.Create(destinationPath, True)
    End If

    mover.Source = New System.Messaging.MessageQueue(sourcePath)
    mover.Destination = _
        New System.Messaging.MessageQueue(destinationPath)
    System.Messaging.MessageQueue.Delete(destinationPath)

    mover.Source.Send("some message", _
        System.Messaging.MessageQueueTransactionType.Single)

    mover.Move()

    MessageBox.Show("Move complete.")
Catch
    MessageBox.Show("Didn't move the message.")
End Try

// C#
try
{
    TransactionComponent.MessageMover mover;
    mover = new TransactionComponent.MessageMover();
    string sourcePath = ".\\SourceQueue";
    string destinationPath = ".\\DestinationQueue";

    if (System.Messaging.MessageQueue.Exists(sourcePath))
    {
        System.Messaging.MessageQueue queue =
            new System.Messaging.MessageQueue(sourcePath);
        if (!queue.Transactional)
        {
            System.Messaging.MessageQueue.Delete(sourcePath);
            System.Messaging.MessageQueue.Create(sourcePath, true);
        }
    }
    else
    {
        System.Messaging.MessageQueue.Create(sourcePath, true);
    }

    if (System.Messaging.MessageQueue.Exists(destinationPath))
    {
        System.Messaging.MessageQueue queue =
            new System.Messaging.MessageQueue(destinationPath);
        if (!queue.Transactional)
        {
            System.Messaging.MessageQueue.Delete(destinationPath);
            System.Messaging.MessageQueue.Create(destinationPath,
```

```
                true);
        }
    }
    else
    {
        System.Messaging.MessageQueue.Create(destinationPath, true);
    }

    mover.Source = new System.Messaging.MessageQueue(sourcePath);
    mover.Destination =
        new System.Messaging.MessageQueue(destinationPath);
    System.Messaging.MessageQueue.Delete(destinationPath);

    mover.Source.Send("some message",
        System.Messaging.MessageQueueTransactionType.Single);
    mover.Move();

    MessageBox.Show("Move complete.");
}
catch
{
    MessageBox.Show("Didn't move the message.");
}
```

11. Run the application and click the **Fail** button.
12. In the Control Panel item named **Administrative Tools**, open the C**omputer Management** application. Expand the **Services and Applications** node and then the **Message Queuing** and **Public Queues** nodes. Locate the SourceQueue and DestinationQueue. Confirm that a new message was created and exists in SourceQueue. Even though the message was removed in the **Move** method, the message was returned to the queue when the transaction failed.

Next Steps

The message queues involved in your application may not all reside on the same server. For information on using queues in a domain, see Message Queues and Messaging Technology Backgrounder.

In this example, the information in the queue was a simple string. You may want to move more complicated objects between queues. For more information, see Message Serialization and Introduction to Reading and Retrieving Messages.

See Also

Transactional Message Processing | Creating Queues | MessageQueue Class | Writing Serviced Components

Queue and Message Collections

You can retrieve lists of the queues on your Message Queuing network and the messages they contain by using any of a variety of retrieval methods available in the **MessageQueue** class. You might retrieve lists of queues and messages if you wanted to perform administrative tasks, generate reports about queue contents, or search through the contents of a queue for messages that meet specific criteria.

There are two main ways you can retrieve both messages and message queues: you can retrieve a static snapshot of the messages or queues on the network, or you can iterate through messages and queues using an enumerator. Retrieving a static list of queues or messages is faster than retrieving an enumeration but does not give you as much accuracy in or control over the resulting set of information. You might use a static snapshot of retrieval if you need to perform an administrative task on all public queues in your network.

Enumerators give you finer control over how you interact with the retrieved results. Using an enumerator, you can locate a queue or message that meets certain criteria, instead of evaluating each and every item in the returned collection. For example, you might use an enumerator if you want to review the contents of a queue and work with only those messages for which a particular property has been set to **true**.

Message Queues Retrieval

You can retrieve information about message queues in the following ways:

- You can retrieve a static array of all of the public or private queues on the network.
- You can retrieve a static subset of all the public queues on the network by specifying certain criteria such as the date and time the queue was created or modified, or by specifying a category, label, or machine by which to retrieve queues.
- You can iterate queues on the network using an enumerator, or you can iterate through a subset of all the queues on the network by specifying criteria such as machine name, date and time created, and category.

You can also use the Exists method to determine whether a queue you are interested in exists. The **Exists** method searches for a specific queue by a path you define.

For instructions on retrieving lists of message queues, see Retrieving Queues.

Message Retrieval

When you retrieve messages in an array or enumerator, you do not actually pull those messages off the queue as you do when you read or receive messages. Instead, you retrieve information about the items in the queue, while the actual messages remain available to the users who were intended to receive them.

You can retrieve messages in the following ways:

- You can retrieve a static array of all the messages in a queue.
- You can iterate messages in a queue using an enumerator.

For instructions on retrieving lists of messages, see Retrieving Messages.

Working with Items in an Enumerator

After you create an enumeration of messages or queues, the enumerator is conceptually positioned before the first item of the enumeration. You can call the **GetNext** method to move to the first item in the list and to move through subsequent items. You can also use the **Current** method to return the item you are currently positioned on in the enumeration.

See Also

Retrieving Queues | Retrieving Messages

Retrieving Messages

You can use either static or dynamic retrieval mechanisms to retrieve a list of messages. When you retrieve a static list of messages, the system returns an array of Message objects representing all messages in the queue.

When you retrieve a dynamic list of messages, the system returns a MessageEnumerator object representing all messages in the queue. A **MessageEnumerator** object is a cursor, initialized to the head of a dynamic list. The list order is the same as the order of the messages in the queue, according to message priority. You can move the cursor to the first message in the queue by calling the MoveNext method. After the enumerator has been initialized, you can use **MoveNext** to step forward through the remaining messages. You can specify whether to wait for a message to become available by passing a time-out into the **MoveNext** method.

Because the enumerator is dynamic, it can access a message that is appended beyond the cursor's current position (for example, due to low priority). The enumerator cannot access a message that is inserted before the cursor's current position. It is not possible to step backward with a **MessageEnumerator**. A cursor allows forward-only movement. The Reset method enables you to place the cursor back at the beginning of the queue.

> **Note** If you instantiate a **MessageQueue** with DenySharedReceive set to **true**, no other application can modify the messages in your enumerator while you have the connection to the queue.

To retrieve a static list of messages

1. Create an instance of the **MessageQueue** component and set its Path property to the queue to which you want to refer. For more information, see Creating MessageQueue Component Instances.

   > **Note** If you created your component from Server Explorer, the **Path** property is set automatically to the queue path for that queue.

2. Create an array that references the **Message** class to hold the results of your query.
3. Call the GetAllMessages method.
4. Assign the results to the array you created.

   The following code shows how you might use the **GetAllMessages** function to retrieve the messages from a queue and display the message labels in a list box. This example assumes that a **MessageQueue** component instance has been added to the application.

```
' Visual Basic
Private Sub button1_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles button1.Click
   Me.MessageQueue1.Path = ".\MyQueue"
   Dim msg() As System.Messaging.Message
   Dim i As Integer
   ' Retrieve the messages.
   msg = MessageQueue1.GetAllMessages()
   ' Clear the current contents of the list.
   Me.ListBox1.Items.Clear()
   ' Display the results.
   For i = 0 To msg.Length - 1
      Me.ListBox1.Items.Add(msg(i).Label)
   Next
End Sub

// C#
private void button1_Click(System.Object sender, System.EventArgs e)
{
   messageQueue1.Path = ".\\MyQueue";
   System.Messaging.Message[] msg;
   // Retrieve the messages.
   msg = messageQueue1.GetAllMessages();
   // Clear the current contents of the list.
   this.listBox1.Items.Clear();
   // Display the results.
```

```
    for (int i = 0; i < msg.Length; i++)
    {
       this.listBox1.Items.Add(msg[i].Label);
    }
}
```

To retrieve a dynamic list of messages

1. Create an instance of the **MessageQueue** component and set its **Path** property to the queue to which you want to refer. For more information, see Creating MessageQueue Component Instances.

   Note If you created your component from Server Explorer, the **Path** property is set automatically to the queue path for that queue.

2. Create a MessageEnumerator object to hold the results of your query.
3. Call the GetEnumerator method on the **MessageQueue** class.
4. Assign the results to the **MessageEnumerator** object. Your code might look like this:

```
' Visual Basic
Dim mq As New System.Messaging.MessageQueue(".\MyQueue")
Dim msgEnum As System.Messaging.MessageEnumerator
msgEnum = CType(mq.GetEnumerator, System.Messaging.MessageEnumerator)

// C#
System.Messaging.MessageQueue mq = new System.Messaging.MessageQueue();
System.Messaging.MessageEnumerator msgEnum;
mq.Path = @".\MyQueue";
msgEnum = (System.Messaging.MessageEnumerator)(mq.GetEnumerator());
```

Queue and Message Collections | Retrieving Queues

Retrieving Queues

You can use either static or dynamic retrieval mechanisms to retrieve a list of queues. When you retrieve a static list of queues, the system returns a MessageQueue object with the results of your query. When you retrieve a dynamic list of queues, the system returns a MessageQueueEnumerator object with the results of the query.

Unlike the MessageEnumerator, which returns messages according to their order in a queue, the **MessageQueueEnumerator** does not return queues in any order. This is because queues on a network are not defined in order — they are not ordered, that is, by computer, label, or other user-accessible criteria. You can move the cursor to the first queue of the enumeration by calling the MoveNext method. After the enumerator has been initialized, you can use **MoveNext** to step forward through the remaining queues.

It is not possible to step backward with a **MessageQueueEnumerator**. A cursor only allows forward movement through the queue enumeration. However, you can call the Reset method to reset the enumeration and put the cursor at the beginning of the list again. Because the enumerator is dynamic, it can access a queue that is appended beyond the cursor's current position. A queue that is inserted before the cursor's current position cannot be accessed without first calling **Reset**.

Because the **GetPublicQueues**, **GetPrivateQueuesByMachine**, and **GetMessageQueuesEnumerator** methods are static, you do not need to create an instance of the **MessageQueue** class before calling the method.

To retrieve a static list of public or private queues

1. Create an array of type **MessageQueue** to hold the results of your query.
2. Call the appropriate method on the **MessageQueue** class:
   - To retrieve all public queues without criteria, call the GetPublicQueues method.
   - To retrieve public queues with criteria, set the **Criteria** parameter to the appropriate value and call the GetPrivateQueuesByMachine method.
   - To retrieve only those public queues that share a category GUID, call the GetPublicQueuesByCategory method and specify the category GUID as the parameter.
   - To retrieve only those public queues that share a label, call the GetPublicQueuesByLabel method and specify the label as a parameter.
   - To retrieve only those public queues on a specific machine, call the GetPublicQueuesByMachine method and specify the machine name as a parameter.
3. Assign the results to the array.

   For example, the following code shows how you might use a list box to display the label of all retrieved public queues on the local machine:

```
' Visual Basic
Private Sub button1_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles button1.Click
   Dim mqlist() As System.Messaging.MessageQueue
   Dim i As Integer
   ' Retrieve queues on the local machine.
   mqlist = System.Messaging.MessageQueue.GetPublicQueuesByMachine(".")
   ' Clear the current contents of the list.
   Me.ListBox1.Items.Clear()
   ' Display the results.
   For i = 0 To mqlist.Length - 1
      Me.ListBox1.Items.Add(mqlist(i).Path)
   Next
End Sub

// C#
private void button1_Click(System.Object sender, System.EventArgs e)
{
   System.Messaging.MessageQueue[] mqlist;
   // Retrieve public queues.
   mqlist = System.Messaging.MessageQueue.GetPublicQueuesByMachine(
```

```
        ".");
    // Clear the current contents of the list.
    this.listBox1.Items.Clear();
    // Display the results.
    for (int i = 0; i < mqlist.Length; i++)
    {
        this.listBox1.Items.Add(mqlist[i].Path);
    }
}
```

To retrieve a dynamic list of queues

1. Create a MessageQueueEnumerator object to hold the results of your query.
2. Call the GetMessageQueueEnumerator method on the **MessageQueue** class.
3. To retrieve a subset of the queues on the network, set the Criteria parameter to the appropriate value.
4. Set the results to the **MessageQueueEnumerator** object you created. Your code might look like this:

```
' Visual Basic
Dim mqEnum As System.Messaging.MessageQueueEnumerator
mqEnum = System.Messaging.MessageQueue.GetMessageQueueEnumerator()

// C#
System.Messaging.MessageQueueEnumerator mqEnum;
mqEnum = System.Messaging.MessageQueue.GetMessageQueueEnumerator();
```

Message Queue Security

Microsoft Windows Message Queuing takes advantage of the various built-in security features of the Windows 2000 operating system. Specifically, Message Queuing uses access control, authentication, encryption, and auditing for security:

- Access control is used to restrict user access to Message Queuing objects, and is implemented by assigning security descriptors to objects. Message Queuing objects include computer (MSMQ), queue, routing link, and Message Queuing Settings objects. A security descriptor lists the users and groups that are granted or denied access to an object, and the specific permissions assigned to those users and groups.
- Authentication is implemented using public key certificates, the Kerberos V5 security protocol, and Windows NTLM (for compatibility with Message Queuing 1.0 running on Windows NT 4.0). Public key certificates are used for message authentication, which verifies the sender of a message (the client) to a Message Queuing server. Kerberos V5 and NTLM are used for server authentication, which verifies a Message Queuing server to a client.
- Encryption is implemented using both public key (asymmetric) and secret key (symmetric) algorithms. Encryption is used by Message Queuing applications to encrypt messages sent between Message Queuing computers.
- Auditing is used to record which users attempt to access Message Queuing objects in Active Directory. The security descriptor for an object specifies the various access events to be audited for the object.

By managing security properties for objects, you can set permissions, assign ownership, and monitor user access. For more information on the specifics of security in Message Queuing, see "Security Message Queuing" in the Windows 2000 or Windows NT Message Queuing documentation, or search MSDN Online for articles on configuring security in your **MessageQueue** components.

Troubleshooting MessageQueue Components

You may encounter the following situation while working with the **MessageQueue** component:

Client is Not Recognized by Microsoft MessageQueue Service

If you are sending messages from a server configured as a Windows 2000 dependent client to a Message Queue enterprise and the enterprise server is a Windows NT version 4.0 server with Service Pack 4, you might receive the following error when you send a message to the queue:

> "Service not installed."

To solve this problem

- Install Service Pack 6 or later on the Windows NT 4.0 server. For more information, see the Downloads section of the Microsoft Web site (http://www.microsoft.com/).

Creating File System and Timer Components

File system and scheduling components allow you to interact with file system and directory-level resources and raise events at scheduled intervals. **FileSystemWatcher** component instances allow you to watch for changes to directories and files and react when they occur. The Timer component allows you to set up simple event-raising schedules and carry out associated processing.

Introduction to Monitoring File System Events

You use the **FileSystemWatcher** component to monitor a file system and react when changes to the directories or files it contains occur. This makes it possible for you to quickly and easily launch business processes when certain files or directories are created, modified, or deleted. For example, suppose you and a group of coworkers are collaborating on a document that is stored on a shared directory on your server. Using an instance of the **FileSystemWatcher** component, you can program your application to watch for changes to the contents of that shared directory. When a change is detected, the component can run procedures that notify each of the group members via e-mail.

> **Note** The **FileSystemWatcher** component is designed to watch for changes within a directory, not to changes to the root directory's attributes themselves. For example, if you are watching a directory called c:\MyProjects, the component will monitor changes within the directory but not changes to the root directory itself.

You can configure the component to watch either an entire directory and its contents or a specific file or set of files within a given directory. The **FileSystemWatcher** component raises an event whenever a file or subdirectory within the specified root directory is created, deleted, renamed, or changed in some other way. The types of changes that the component monitors include changes in the file's or subdirectory's attributes, size, last write time, last access time, and security settings.

> **Security Note** A denial-of-service attack is possible if a malicious program gains access to a directory your **FileSystemWatcher** component is monitoring and generates so many changes that the component cannot manage them. Follow the recommendations in Considerations for File Changes on High-Volume Systems and use access control lists properly to reduce the risk of a denial-of-service attack. For more information, see Access Control.

Directory-Level Events

When changes occur within a root directory or to a file your application is monitoring, one or more events are raised, stored in a buffer, and ultimately passed to your component for processing. The **FileSystemWatcher** component gives you access to the following events:

- Created — raised whenever a directory or file is created.
- Deleted — raised whenever a directory or file is deleted.
- Renamed — raised whenever the name of a directory or file is changed.
- Changed — raised whenever changes are made to the size, system attributes, last write time, last access time, or security permissions of a directory or file.

> **Note** Although some common occurrences, such as copying or moving a file, do not correspond directly to an event, these occurrences do cause events to be raised. When you copy a file, the system raises a **Created** event in the directory to which the file was copied but does not raise any events in the original directory. When you move a file, the server raises two events: a **Deleted** event in the source directory, followed by a **Created** event in the target directory.

Each change to a file in a directory raises a separate event. If a user makes multiple changes to a single file, the application raises a separate event for each change. For example, if you are watching a directory that contains five files and the security permissions for all of the files suddenly change, you will receive five **Changed** events. If the user renames and assigns new security permissions to each of those files, you will receive 10 event notifications — a **Changed** event and a **Renamed** event for each of the five files.

Creating FileSystemWatcher Component Instances

You create an instance of the **FileSystemWatcher** component when you want to build file system monitoring into your application. **FileSystemWatcher** components allow you to connect to directories and watch for specific changes within them, such as the creation of new files, addition of subdirectories, and renaming of files or subdirectories.

You can add an instance of the **FileSystemWatcher** component to Windows Forms, Web Forms, and component classes. **FileSystemWatcher** components have no visual user interface. If you add an instance of the **FileSystemWatcher** component to a visual designer (such as the Windows Forms Designer), the component appears in a small area below the bottom border of the form. This area is known as the component tray and acts as a place to display all of the nonvisual items associated with the form.

> **Note** Nonvisual classes that inherit from **System.ComponentModel.Component** support a visual design surface similar to the component tray, on which your **FileSystemWatcher** component and other components are arranged. The arrangement of items on this designer is not important, as the interface you see will never be displayed to the application's end users.

There are several ways you can create an instance of the **FileSystemWatcher** component:

- You can drag an instance of the **FileSystemWatcher** component from the **Components** tab of the Toolbox to a form or other designer.
- You can create an instance of the **FileSystemWatcher** component in code.

> **Note** Unlike many of the other components on the Components tab of the Toolbox, **FileSystemWatcher** components are not represented in Server Explorer, so you cannot create instances of the component from that window.

To create an instance of the FileSystemWatcher component from the Toolbox

1. Access the **Components** tab of the Toolbox.
2. Select the **FileSystemWatcher** icon and drag it to the designer surface for your form or component.
3. Configure your component. For more information, see Configuring FileSystemWatcher Component Instances.

To create an instance of the FileSystemWatcher component programmatically

1. Create an instance of the **FileSystemWatcher** base class in code. Your code might look like this:

```
' Visual Basic
Dim myWatcher As New System.IO.FileSystemWatcher()

// C#
System.IO.FileSystemWatcher myWatcher =
   new System.IO.FileSystemWatcher();
```

2. Configure any other necessary properties for your component. For more information, see Configuring FileSystemWatcher Component Instances.

See Also

Configuring FileSystemWatcher Component Instances | Introduction to Monitoring File System Events

Configuring FileSystemWatcher Component Instances

There are several properties you set for your **FileSystemWatcher** component instances to determine how they behave. These properties determine what directories and subdirectories the component instance will monitor and the exact occurrences within those directories that will raise events.

Specifying the Directories to Watch

You use two properties to determine what directories the **FileSystemWatcher** component should watch: Path and IncludeSubdirectories.

Path indicates the fully qualified path of the root directory you want to watch. This can be in standard directory path notation (c:\directory) or in UNC format (\\server\directory). You can set the **Path** property on an existing component instance, as shown in the following code:

```
' Visual Basic
Dim MyWatcher As New System.IO.FileSystemWatcher()
MyWatcher.Path = "c:\"

// C#
System.IO.FileSystemWatcher MyWatcher = new System.IO.FileSystemWatcher();
MyWatcher.Path = "c:\\";
```

The **IncludeSubdirectories** property indicates whether subdirectories within the root directory should be monitored. If the property is set to **true**, the component watches for the same changes in the subdirectories as it does within the main directory the component is watching.

Specifying the Changes to Watch

In addition to specifying the directories and subdirectories to watch, you can indicate what specific files and types of changes you are interested in watching for. In part, you determine the changes to watch for by defining handlers for only those events in which you are interested. For example, if you only want to be notified when files are created, you would only handle the Created event. However, you can set a series of properties that restrict the component's activities even further.

You can use the Filter property to indicate a wildcard matching pattern that restricts the component to watching only certain files or directories within the root directory. For example, if you want to watch for the creation of text files within the root, you could set the Filter property to "*.txt" and then create a handler for the **Created** event. You can set the filter to any value.

> **Note** The **FileSystemWatcher** component is designed to watch for changes within a directory, not to changes to the directory's attributes themselves. For example, if you are watching a directory called c:\MyProjects, the component will monitor changes within the directory but not changes to the directory itself.

You can also use the NotifyFilter property to further restrict the changes that are reacted to. You can set the **NotifyFilter** property to watch for changes to directory names, files names, or both. In addition, the **NotifyFilter** property contains a series of values that restrict the **Changed** event. The **Changed** event has the potential to raise a large number of events, because it will raise an event each time any change is made to the file in question; some standard operations like copying and moving files will actually cause several file change events to be raised as various attributes such as size, last write, and last access are altered.

The **NotifyFilter** property limits the number of file or directory changes for which the component instance will raise events. You can set up your component so that it will raise events only when a file or directory name changes, when the attributes of an item in the main directory change, when a file's size changes, when its last write or last access time changes, or when security access to a file or directory rights change. These values are all part of the **NotifyFilters** enumeration. You can set multiple changes to watch for by using a **BitOr** (for Visual Basic) or **|** (for Visual C#) operator, as shown in the example below.

> **Note** You must set the EnableRaisingEvents property to **true** in order for the **FileSystemWatcher** component to start monitoring for changes.

To configure an instance of the FileSystemWatcher component

1. Create an instance of the **FileSystemWatcher** component. For more information, see Creating FileSystemWatcher Component Instances.
2. Set the **Path** property to the fully qualified path of the root directory you want to watch.

   > **Tip** You can enter this as a standard file path or a UNC path.

3. Set any of the optional properties for your instance.

Scenario	Property	Value
To watch for changes to a specific file or subdirectory name within the root	**Filter**	A wildcard filter expression that restricts the monitoring activities of the instance
To watch for changes within any subdirectories the root directory contains	**IncludeSubdirectories**	**true** or **false**
To watch for only specific changes to a file or subdirectory when handling the **Changed, Renamed, Deleted,** or **Created** events	**NotifyFilter**	Any of the available values in the NotifyFilters enumeration

4. Enable your component instance by setting the EnableRaisingEvents property to **true**.

For example, suppose you want to create a **FileSystemWatcher** instance that watches a drop directory called "reports" for the creation of new .txt files. You also want to monitor changes to existing reports that rerun dynamically when data changes. You would set up your component as follows:

```
' Visual Basic
' This needs to be declared in a place where it will not go out of scope.
' For example, it would be a class variable in a form class.
Dim MyWatcher As New System.IO.FileSystemWatcher()
' This code would go in one of the initialization methods of the class.
MyWatcher.Path = "c:\"
' Watch only for changes to *.txt files.
MyWatcher.Filter = "*.txt"
MyWatcher.IncludeSubdirectories = False
' Filter for Last Write changes.
MyWatcher.NotifyFilter = System.IO.NotifyFilters.LastWrite
' Example of watching more than one type of change.
MyWatcher.NotifyFilter = _
   System.IO.NotifyFilters.LastAccess Or System.IO.NotifyFilters.Size
' Enable the component to begin watching for changes.
MyWatcher.EnableRaisingEvents = True

// C#
// This needs to be declared in a place where it will not go out of scope.
// For example, it would be a class variable in a form class.
System.IO.FileSystemWatcher MyWatcher = new System.IO.FileSystemWatcher();
// This code would go in one of the initialization methods of the class.
MyWatcher.Path = "c:\\";
// Watch only for changes to *.txt files.
MyWatcher.Filter = "*.txt";
MyWatcher.IncludeSubdirectories = false;
// Enable the component to begin watching for changes.
MyWatcher.EnableRaisingEvents = true;
// Filter for Last Write changes.
MyWatcher.NotifyFilter = System.IO.NotifyFilters.LastWrite;
// Example of watching more than one type of change.
MyWatcher.NotifyFilter =
   System.IO.NotifyFilters.LastWrite | System.IO.NotifyFilters.Size;
```

Creating FileSystemWatcher Component Instances | Introduction to Monitoring File System Events

Creating Handlers for File System Events

The **FileSystemWatcher** component raises four events depending on the types of changes that occur in the directory it is watching. These events are:

- Created — raised whenever a directory or file is created.
- Deleted — raised whenever a directory or file is deleted.
- Renamed — raised whenever the name of a directory or file is changed.
- Changed — raised whenever changes are made to the size, system attributes, last write time, last access time, or NTFS security permissions of a directory or file.

> **Note** You can use the NotifyFilter property to limit the amount of events the **Changed** event raises. For more information, see Configuring FileSystemWatcher Component Instances.

For each of these events, you can define handlers that automatically call methods in your code when a change occurs. An event handler is a method that is bound to an event for a component, form, or control. Each event handler provides two parameters that allow you to handle the event properly — the *sender*, which provides an object reference to the object responsible for the event, and the *e* parameter, which provides an object for representing the event and its information.

There are several ways you can create an event handler for an instance of the **FileSystemWatcher** component, but the simplest way is to let Visual Studio .NET create most of the code for you automatically. When you double-click your **FileSystemWatcher** component instance in the designer, Visual Studio opens the Code Editor and creates an event handler for both the **Changed** event and the blank procedure it calls. You can then fill in the processing that you want to occur in the procedure. You can also create your own handlers to handle the other events.

For more information on event handlers, see Event Handlers in Visual Basic and Visual C#.

To create a default handler for the Changed event

1. Create an instance of the **FileSystemWatcher** component. For more information, see Creating FileSystemWatcher Component Instances.
2. Set the necessary properties for the component. For more information, see Configuring FileSystemWatcher Component Instances.
3. From the designer, double-click the **FileSystemWatcher** component for which you want to create a handler.

   > **Note** The Code Editor appears and two items are added to your code: the handler that creates and registers a delegate and calls the procedure, and a blank procedure for the **Changed** event.

4. In the blank procedure for the **Changed** event, define code to take action when this event is called.

To create a handler for a FileSystemWatcher event

1. Create an instance of the **FileSystemWatcher** component. For more information, see Creating FileSystemWatcher Component Instances.
2. Set the necessary properties for the component. For more information, see Configuring FileSystemWatcher Component Instances.
3. Create the appropriate procedure that will be called and define the code you want to process the entries. The following example shows an event handler for the **Changed** event.

```
' Visual Basic
Private Sub myWatcher_Changed(ByVal sender As System.Object, _
   ByVal e As System.IO.FileSystemEventArgs)
   Dim pathChanged As String
   pathChanged = e.FullPath
End Sub

// C#
private void myWatcher_Changed(object sender,
System.IO.FileSystemEventArgs e)
{
   string pathChanged = e.FullPath;
}
```

4. Assign an instance of FileSystemEventHandler to the event for your component. This example adds the **Changed** event handler defined in step 3.

```
' Visual Basic
AddHandler myWatcher.Changed, _
   New System.IO.FileSystemEventHandler(AddressOf Me.myWatcher_Changed)

// C#
myWatcher.Changed +=
   new System.IO.FileSystemEventHandler(this.myWatcher_Changed);
```

Creating FileSystemWatcher Component Instances | Configuring FileSystemWatcher Component Instances | Introduction to Monitoring File System Events

Considerations for File Changes on High-Volume Systems

Your **FileSystemWatcher** component has the potential to receive an enormous number of events, particularly if you have set it to watch a very high-traffic directory. This can cause problems, as the **FileSystemWatcher** component can only receive event notifications at a manageable rate. If the rate at which events are coming in exceeds the rate at which the component can receive them, the excess events are stored in a buffer that is then passed to the component. The component translates each entry in the buffer to an event to be raised to the user's code. This buffer can cause a problem in that it can overflow. If the number of changes in a directory is so large that they cannot all fit in the buffer, the operating system will issue a "blanket" notification, and the component will raise an exception.

> **Security Note** A denial-of-service attack is possible if a malicious program gains access to a directory your **FileSystemWatcher** component is monitoring and generates so many changes that the component cannot manage them. Follow the recommendations in this Help topic and use access control lists properly to reduce the risk of a denial-of-service attack. For more information, see Access Control.

To avoid this problem, you should do several things. First, you should set your buffer to an appropriate size for the approximate number of events you expect to receive. By default, the buffer is set to a size of 4 KB. A 4 KB buffer can track changes on approximately 80 files in a directory. Each event takes up 16 bytes in the buffer, plus enough bytes to store the name of the file, in Unicode (2 bytes per character), that the event occurred on. You can use this information to approximate the buffer size you will need.

You reset the buffer size by setting the InternalBufferSize property in the Properties window. If you are using Microsoft Windows 2000, you should increase the buffer size in increments of 4 KB, because this corresponds to the operating system's default page size. With any other operating system, you should increase the buffer size in increments that correspond to the operating system's default page size.

> **Tip** If you are unsure of the default page size for the operating system you are using, the safest way to proceed is to just double the original size of the buffer. This will maintain the original interval needed for your operating system.

In addition to setting an appropriate buffer size, you can use the following three properties to control the amount of information that the buffer receives:

- Use the NotifyFilter property to determine whether the **FileSystemWatcher** component looks for all changes or only specified changes in the watched directory.
- Use the IncludeSubdirectories property to indicate whether or not you want to include the subdirectories of the directory you are watching. If you turn this off when you do not need it, you will receive fewer events than when it is turned on.
- If you have set the **FileSystemWatcher** component to watch for the **Changed** event, you can use the **NotifyFilter** property to specify only those events in which you are interested.

  > **Note** Although you can also use the Filter property to specify files or subdirectories that you want watched, this property is applied after changes are added to your buffer and will not reduce the buffer size at all. Instead, use the **NotifyFilter** property to control the amount of information written to the buffer.

Configuring FileSystemWatcher Component Instances | Introduction to Monitoring File System Events

Waiting Until Specified File System Events Occur

In addition to using the **FileSystemWatcher** component to immediately monitor a specific directory, you can use the WaitForChanged method to wait until a specific event occurs and then continue with execution of the thread. For example, if you are working with a Web-based news application, you might create an admin portion of the site where users upload their news stories. You could use the **WaitForChanged** method to watch that directory until the last access date changes, and then begin processing the news directory for new articles.

You specify the type of change to watch for by setting the value of a WatcherChangeType enumeration. The possible values are **Created**, **Changed**, **Renamed**, **Deleted**, or **All**. Setting the value to **All** watches for any change to the directory. You can also specify a timeout period if you only want to wait a certain period of time for the event to occur.

The **WaitForChanged** method returns an object of type WaitForChangedResult. This class contains specific information on the type of change that occurred in the directory. You can access information such as Name, OldName, and TimedOut on this object to find out more about the change.

WaitForChanged is a synchronous method. If you use it in a Windows Form application, the application would stop responding if the method was used on the UI thread instead of the worker thread. For more information on threading issues in Visual Basic .NET, see Multithreading in Visual Basic .NET.

To wait for changes

1. Create and configure your **FileSystemWatcher** component instance to indicate the directory you want to watch. For more information, see Creating FileSystemWatcher Component Instances or Configuring FileSystemWatcher Component Instances.
2. In the Code Editor, create an instance of the **WaitForChangedResult** class.

```
' Visual Basic
Dim result As System.IO.WaitForChangedResult

// C#
System.IO.WaitForChangedResult result;
```

3. On your **FileSystemWatcher** component instance, specify the type of event it is waiting for by setting the value of the **WaitForChanged** property to one of the values of the WatcherChangeTypes enumeration.

```
' Visual Basic
fileSystemWatcher1.WaitForChanged(System.IO.WatcherChangeTypes.All)

// C#
fileSystemWatcher1.WaitForChanged(System.IO.WatcherChangeTypes.All);
```

   Tip You can use an overloaded form of the WaitForChanged method to specify a timeout period as a second parameter.

4. Specify the actions you want to take when the change for which you are watching occurs. For more information, see Creating Handlers for File System Events.

The following code shows how to notify a user that a file needs to be deleted, then wait for the **Deleted** event to be raised. This code watches the personal folder of the user.

```
' Visual Basic
Console.WriteLine("Please delete OldNote.txt.")
Dim directory As String
directory = Environment.GetFolderPath(Environment.SpecialFolder.Personal)
Dim watcher As New System.IO.FileSystemWatcher(directory, "OldNote.txt")
result = watcher.WaitForChanged(System.IO.WatcherChangeTypes.Deleted)
Console.WriteLine("Thanks for deleting OldNote.txt.")

// C#
Console.WriteLine("Please delete OldNote.txt.");
string directory =
   Environment.GetFolderPath(Environment.SpecialFolder.Personal);
```

```
System.IO.FileSystemWatcher watcher =
   new System.IO.FileSystemWatcher(directory,"OldNote.txt");
result = watcher.WaitForChanged(System.IO.WatcherChangeTypes.Deleted);
Console.WriteLine("Thanks for deleting OldNote.txt.");
```

Walkthrough: Reacting to File System Events

The procedures in this topic walk you through the process of creating a **FileSystemWatcher** component, pointing it to a directory on your local computer, and then using the FileSystemWatcher.Filter property to watch only for changes to text files. You will create an event handler that responds when the FileSystemWatcher.Created event and FileSystemWatcher.Changed event are raised, and you will use a form to display the notifications that result from these events.

Create the form and components you need for the application

In this procedure, you create a Windows Form and a **FileSystemWatcher** component instance that will work together to react to directory-level events.

1. From the **New Project** dialog box, create a Visual Basic or C# Windows Application, and name it **MyWatcher**.
2. From the **Windows Forms** tab in the Toolbox, drag two **Label** controls to the designer surface.
3. Click the **Components** tab in the Toolbox, and then drag the **FileSystemWatcher** icon to the designer surface for your component. By default, this component is named **FileSystemWatcher1**.

To set properties for your FileSystemWatcher component

In this procedure, you set several properties for your component to determine what it will watch. These settings cause the component to watch the specified directory on your local computer and to watch for the creation of files ending in the .txt file name extension.

1. Click the **FileSystemWatcher** component you created in the previous procedure, and view its properties in the Properties window.
2. Set the component's name to **myWatcher**.
3. Use the Path property to set the **FileSystemWatcher** component to watch a directory on your local computer. For example, on a computer running Microsoft® Windows® 2000, you might enter the following into the **Path** property to set the component to watch your My Documents directory:

   ```
   C:\Documents and Settings\yourusername\My Documents\
   ```

   Tip For the purposes of this example, you can use any directory you want on your local computer.

4. Set the **Filter** property to ***.txt** to have the component watch only those files ending in the .txt file name extension.

Write the necessary code for your component

In this procedure, you will define two event handlers for your component that define the processing that should occur whenever the **Changed** and **Created** events are raised.

1. Double-click the **FileSystemWatcher** component. The Code Editor appears and a default event handler for the **Changed** event appears.

   Note For more information, see Event Handling in Windows Forms.

2. Use the following code to display a simple text string that will verify that your event was raised:

   ```
   ' Visual Basic
   Private Sub myWatcher_Changed(ByVal sender As System.Object, _
      ByVal e As System.IO.FileSystemEventArgs) Handles myWatcher.Changed
      Me.Label1.Text = "Changes made to: " & e.FullPath
   End Sub

   // C#
   private void myWatcher_Changed(object sender,
      System.IO.FileSystemEventArgs e)
   {
      label1.Text = "Changes made to: " + e.FullPath;
   }
   ```

3. Create the event handler for the **Created** event that specifies what your application should do whenever the component

raises this event. For information on creating event handlers, see Creating Event Handlers on the Windows Forms Designer. Add code as shown to display the full path of the newly created file.

```
' Visual Basic
Private Sub myWatcher_Created(ByVal sender As System.Object, _
   ByVal e As System.IO.FileSystemEventArgs) Handles myWatcher.Created
   Me.Label2.Text = "The file: " & e.FullPath & _
      " has been added to your directory"
End Sub

//C#
private void myWatcher_Created(object sender,
   System.IO.FileSystemEventArgs e)
{
   label2.Text = "The file: " + e.FullPath +
      " has been added to your directory.";
}
```

4. Save all files, and then build and run your application.

To test your FileSystemWatcher component

In this procedure, you will manually make changes in the directory your component is watching so that you can force the event handler to raise the **Changed** and **Created** events.

1. Run the application you created in the previous procedure.
2. Use Windows Explorer to find the directory that you set your **FileSystemWatcher** component to watch.
3. Open Notepad, and then create a new text file. Save this file to the directory you located in step 2 and close the file.

   Note This should raise the **Created** and **Changed** events and run the handler you defined.

4. Return to the form. You should see the created message in the label.
5. Open the text file you created, type a few lines of text, and save it again.

   Note This should raise the **Changed** event and run the handler you defined.

6. Return to the form. You should see the change message in the label.

Troubleshooting FileSystemWatcher Components

You may encounter the following situations while working with the **FileSystemWatcher** component:

UNC Path Names Not Accepted on Windows NT 4.0 Computers

If you are working with a **FileSystemWatcher** component on a Windows NT version 4.0 computer and trying to set its path to monitor file system activity on a different Windows NT version 4.0 computer, you will not be able to specify a UNC-based path value in the Path property to point to the computer in question. You can only set UNC-based values when working on Windows 2000 computers.

Cannot Watch Windows 95 or Windows 98 Directories

If you set your **FileSystemWatcher** component to reference a directory on a Windows 95 or Windows 98 computer, you will receive an error about an invalid directory path when the project runs. When using **FileSystemWatcher**, you cannot watch directories on computers running Windows 95 or Windows 98.

Multiple Created Events Generated for a Single Action

You may notice in certain situations that a single creation event generates multiple Created events that are handled by your component. For example, if you use a **FileSystemWatcher** component to monitor the creation of new files in a directory, and then test it by using Notepad to create a file, you may see two **Created** events generated even though only a single file was created. This is because Notepad performs multiple file system actions during the writing process. Notepad writes to the disk in batches that create the content of the file and then the file attributes. Other applications may perform in the same manner. Because **FileSystemWatcher** monitors the operating system activities, all events that these applications fire will be picked up.

> **Note** Notepad may also cause other interesting event generations. For example, if you use the **ChangeEventFilter** to specify that you want to watch only for attribute changes, and then you write to a file in the directory you are watching using Notepad, you will raise an event . This is because Notepad updates the **Archived** attribute for the file during this operation.

Unexpected Events Generated on Directories

Changing a file within a directory you are monitoring with a **FileSystemWatcher** component generates not only a Changed event on the file but also a similar event for the directory itself. This is because the directory maintains several types of information for each file it contains — the names and sizes of files, their modification dates, attributes, and so on. Whenever one of these attributes changes, a change is associated with the directory as well.

Introduction to Server-Based Timers

Server-based timers allow you to specify a recurring interval at which an event will be raised in your application. You can then handle this event to provide regular processing. For example, suppose you have a critical server that must be kept running 24 hours a day, seven days a week. You could create a service that uses a timer to periodically check the critical server to ensure that the system is up and running. If the system is not responding, the service can attempt to restart the server or notify an administrator.

> **Note** The interval for server timers is specified in milliseconds.

Server Timers, Windows Timers, and Thread Timers

There are three timer controls in Visual Studio .NET and the .NET Framework — the server-based timer you can see on the Components tab of the Toolbox, the standard Windows-based timer you can see on the Windows Forms tab of the Toolbox, and the thread timer that is only available programmatically. The Windows-based timer has existed in Visual Basic since version 1.0, and has remained essentially unchanged. This timer is optimized for use in Windows Forms applications. The server-based timer is an update of the traditional timer that has been optimized to run in a server environment. The thread timer is a simple, lightweight timer that uses callback methods instead of events and is served by threadpool threads.

There are two types of threads in Win32 architecture: UI threads, and worker threads. UI threads sit idle most of the time and wait for messages to arrive in their message loops. Once they receive a message, they handle it and then wait for the next message to arrive. Alternatively, worker threads are used to perform background processing and do not use message loops. Both the Windows timer and the server-based timer run using an Interval property. The interval of the thread timer is set in the **Timer** constructor. The timers are designed for different purposes, as evidenced by their handling of threads:

- The Windows timer is designed for a single-threaded environment where UI threads are used to perform processing. The accuracy of Windows timers is limited to 55 milliseconds. These traditional timers require that the user code have a UI message pump available and always operate from the same thread, or marshal the call onto another thread. For a COM component, this would be detrimental to performance.
- The server-based timer is designed for use with worker threads in a multi-threaded environment. Because they use a different architecture, server-based timers have the potential to be much more accurate than Windows timers. Server timers can move among threads to handle the raised events.
- The thread timer is useful in scenarios where messages are not pumped on the thread. For example, the Windows-based timer relies on operating-system timer support, and if you are not pumping messages on the thread, the event associated with your timer will not occur. The thread timer is more useful in this case.

The Windows timer is located in the **System.Windows.Forms** namespace, the server timer is located in the **System.Timers** namespace, and the thread timer is located in the **System.Threading** namespace.

Timer Programming Architecture

The **Timer** component uses the System.Timers namespace in the Microsoft .NET Framework. The major class within this namespace pertaining to the **Timer** component is System.Timers.Timer.

Key Programming Elements of Server-Based Timers

The **Timer** component raises an event called Timer.Elapsed. You can create handlers for this event to perform whatever processing needs to occur.

Some of the more important properties and methods of a **Timer** component include the following:

- The Interval property is used to set the time span, in milliseconds, at which events should be raised. For example, an interval of 1000 will raise an event once a second.
- The AutoReset property determines whether the timer continues raising events after the given interval elapses. If set to **true**, the timer continues to recount the interval and raise events. If **false**, it raises one event after the interval elapses and then stops.
- The Start method sets the timer's **Enabled** property to **true**, which allows the timer to begin raising events. If the timer is already enabled, calling the **Start** method resets the timer.
- The Stop method sets the timer's Enabled property to **false**, preventing the timer from raising any more events.

Introduction to Server-Based Timers | Creating Instances of Server-based Timers | Monitoring Server-Based Timers

Creating Instances of Server-Based Timers

You create **Timer** components when you want to build interval-based events into your multi-threaded application. You can add an instance of the **Timer** component to Web Forms, Windows Services, and component classes. If you add an instance of the **Timer** component to a visual designer (such as the Web Forms Designer), the component appears in a small area below the bottom border of the form. This is known as the component tray and acts as a place to display all of the non-visual items associated with the form.

There are two ways you can create an instance of the **Timer** component:

- You can drag an instance of the **Timer** component from the Components tab of the Toolbox to a form or other designer.
- You can create an instance of the **Timer** component in code.

To create a Timer component from the Toolbox

1. Access the **Components** tab of the Toolbox.
2. Select the **Timer** icon, and drag it to the designer surface for your form or component.
3. Set the Interval property for your component instance to the length of time, in milliseconds, after which you want the component to raise an event.
4. Set the Enabled property for your component instance to **true**.

To create a Timer component programmatically

1. Add a reference to the **System.Timers** DLL and import the **System.Timers** namespace into your project.
2. Create an instance of the **Timer** class in code.
3. Set the Interval property for your component instance to the length of time, in milliseconds, after which you want the component to raise an event.
4. Set the Enabled property for your component instance to **true**.

   The following code shows how to create and configure a **Timer** component programmatically.

```
' Visual Basic
Dim myTimer As New System.Timers.Timer()
myTimer.Enabled = True
myTimer.Interval = 3000

// C#
System.Timers.Timer myTimer = new System.Timers.Timer();
myTimer.Enabled = true;
myTimer.Interval = 3000;
```

See Also

Introduction to Server-Based Timers | Monitoring Server-Based Timers | Introduction to the Windows Forms Timer Component

Monitoring Server-Based Timers

The **Timer** component raises an event called Elapsed periodically, based on the interval you specify. You can handle this event to perform the processing you need. For example, suppose that you have an online sales application that continuously posts sales orders to a database. The service that compiles the instructions for shipping operates on a batch of orders rather than processing each order individually. You could use a timer to start the batch processing every 30 minutes.

To create a default handler for the Elapsed event

1. From the designer, double click on the **Timer** component for which you want to create a handler.

   Note The Code Editor appears and two items are added to your code: the handler that creates and registers a delegate and calls the procedure, and a blank procedure for the **Timer.Elapsed** event.

2. In the blank procedure for the **Elapsed** event, define code to run when this event is called.

To create a handler for the Elapsed event programmatically

1. Create an instance of the **Timer** component and set the necessary properties for it to function. For more information, see Creating Instances of Server-Based Timers.
2. Use the AddHandler method to create an event handler for your component that will call the **MyTimer_Elapsed** procedure when the Elapsed event is raised. Your code should look like this:

```
' Visual Basic
AddHandler myTimer.Elapsed, New _
   System.Timers.ElapsedEventHandler(AddressOf Me.myTimer_Elapsed)

// C#
myTimer.Elapsed +=
   new System.Timers.ElapsedEventHandler(myTimer_Elapsed);
```

   Note For more information on this syntax, see Event Handling in Windows Forms.

3. Create the **myTimer_Elapsed** procedure and define the code you want to process the event.

```
' Visual Basic
Private Sub myTimer_Elapsed(ByVal sender As System.Object, ByVal e As System.Timers.Elaps
edEventArgs)
   System.Windows.Forms.MessageBox.Show("Elapsed!", _
      "Timer Event Raised!")
End Sub

// C#
private void myTimer_Elapsed(object sender, System.Timers.ElapsedEventArgs e)
{
   System.Windows.Forms.MessageBox.Show("Elapsed!",
      "Timer Event Raised!");
}
```

The following code shows how you can create a **Timer** component that raises an event every five seconds and displays a message box that alerts you to the event:

```
' Visual Basic
Private Sub CreateTimer()
   Dim Timer1 As New System.Timers.Timer()
   Timer1.Interval = 5000
   Timer1.Enabled = True
   AddHandler Timer1.Elapsed, _
      New System.Timers.ElapsedEventHandler(AddressOf Me.Timer1_Elapsed)
End Sub
```

```
Private Sub Timer1_Elapsed(ByVal sender As System.Object, _
   ByVal e As System.Timers.ElapsedEventArgs)
   System.Windows.Forms.MessageBox.Show("Elapsed!", "Timer Event Raised!")
End Sub

// C#
private void CreateTimer()
{
   System.Timers.Timer Timer1 = new System.Timers.Timer();
   Timer1.Enabled = true;
   Timer1.Interval = 5000;
   Timer1.Elapsed +=
      new System.Timers.ElapsedEventHandler(Timer1_Elapsed);
}

private void Timer1_Elapsed(object sender,
System.Timers.ElapsedEventArgs e)
{
   System.Windows.Forms.MessageBox.Show("Elapsed!",
      "Timer Event Raised!");
}
```

Monitoring Performance Thresholds

Windows performance counters allow your applications and components to publish, capture, and analyze the performance data that applications, services, and drivers provide. You can use this information to determine system bottlenecks and fine-tune system and application performance. For example, you might use a performance counter to track the amount of time required to process an order or query a database, or you might monitor the size of a message queue and write code that performs a specific action whenever the queue reaches a preset limit.

Using the **PerformanceCounter** component and language features in Visual Studio .NET and the Microsoft .NET Framework SDK, you can easily connect to performance counters on both local and remote computers and retrieve values from these counters. You can also write values to existing custom counters (those created with .NET) on the local computer and create your own custom counters on computers that have Windows installed.

Introduction to Monitoring Performance Thresholds

The mechanism by which Windows collects performance data on various system resources is the *performance counter*. Windows contains a pre-defined set of performance counters with which you can interact; some of these are found on all Windows 2000 computers and some are custom to specific applications and are found only on certain computers. Each counter is related to a specific area of system functionality. Examples include counters that monitor a processor's busy time, memory usage, or the number of bytes received over a network connection. You use an instance of the **PerformanceCounter** component to connect directly to existing performance counters and interact with their data in dynamic ways.

A performance counter monitors the behavior of *performance objects* on a computer. These include physical components, such as processors, disks, and memory, and system objects, such as processes and threads. In Visual Studio and the .NET SDK, these performance objects are shown as categories; system counters related to the same performance object are grouped into categories that indicate their common focus. When you create an instance of the **PerformanceCounter** component, you first indicate the category with which the component will interact and then choose a counter to interact with from within that category.

For example, a category of counters on Windows is the Memory category. System counters within this category track data such as bytes available and bytes cached. To deal with bytes cached in your application, you create an instance of the **PerformanceCounter** component and connect it to the Memory category, then pick the appropriate counter in that category (Cached Bytes, in this case).

In some situations, categories are further subdivided into instances. Instances track data about multiple occurrences of the object that a category relates to. It is important to note that instances apply to the category as whole, rather than to individual counters. All counters within a category have each instance defined for the category. For example, the Process category contains instances called "Idle" and "System." Each counter within the Process category specifies data in these two ways, showing information about either idle processes or system processes. The structure of the category and counters looks like this:

Categories, Instances, and Counters

	Category: Process	
	Instance1:Idle	Instance2:System
Counter: Elapsed Time	✓	✓
Counter: Thread Count	✓	✓

As you can see, the Process category contains two instances, so both counters in the category also contain instances of Idle and System. For more information on instances, see Adding and Removing Performance Counter Instances.

Although your system makes available many more categories of counters, the default categories you'll probably interact with most frequently include the Cache, Memory, Objects, PhysicalDisk, Processor, Server, System, and Thread categories.

Performance Counter Data

Performance counters record values about various parts of the system. These values are not stored as entries, but are persisted for as long as a handle remains open for the given category in memory. The process of retrieving data from a performance counter is called *sampling*. When you sample, you either retrieve the immediate value of a counter or a calculated value.

Depending on how a counter is defined, its value might be the most recent aspect of resource utilization, also called the *instantaneous value*, or it might be the average of the last two measurements over the period of time between samples. For example, when you retrieve a value from the Process category's Thread Count counter, you retrieve the number of threads for a particular process as of the last time this was measured. This is an instantaneous value. However, if you retrieve the Memory category's Pages/Sec counter, you retrieve a rate per second based on the average number of memory pages retrieved during the last two samples.

Resource usage can vary dramatically based on the work being done at various times of day. Because of this, performance counters that show usage ratios over an interval are a more informative measurement than averages of instantaneous counter values. Averages can include data for service startup or other events that might cause the numbers to go far out of range for a brief period, thereby skewing results.

The **PerformanceCounter** component provides facilities for the most common Windows performance monitoring requirement, namely, connecting to an existing counter on the server and reading and writing values to it. Additional functionality, such as complex data modeling, is available directly through Windows Performance Monitor. For example, you can use Performance Monitor to chart the data a counter contains, run reports on the data, set alerts, and save data to a log.

Working with Performance Counters in .NET Applications

Using the **PerformanceCounter** component, you can connect to the existing counters installed on the servers to which you have access, or you can create your own custom performance counters. You can read data from any counter, and you can write to your own custom counters.

When you connect to an existing performance counter, you do so by specifying the computer on which the counter exists, the category for the counter, and the name of the counter itself. Additionally, you have the option of specifying the instance of the counter you want to use, if the counter contains more than one instance. You can then read any and all data from the counter. You can also enumerate the existing categories, counters, and instances on the computer by using code, or you can use Server Explorer to see a list of existing counters on the computer.

When you create a new counter, you must specify a completely new category for your local computer. You cannot add a new counter to an existing category or create new counters on a remote computer. However, you can write data to and read data from any custom counters you create.

You can expand the Performance Counters node in Server Explorer to see a list of the counters that exist on that server (by category) and the instances by which they are classified. You can also drag a specific performance counter or instance from Server Explorer to your Component Designer in Microsoft Visual Studio .NET to create an instance of the **PerformanceCounter** component that automatically has its properties set to point to the selected counter.

If you are using a **PerformanceCounter** component in an ASP.NET application, the default settings of the ASPNET user account restrict access to performance counters. The ASPNET user account, by default, can write to but not read from performance counters, and it cannot create new categories. You can use impersonation with the ASPNET account to allow creation of new categories. The impersonation identity must have sufficient privileges to create categories. If your application needs performance counters that can be specified before deployment, they can be created by the deployment project. For more information, see ASP.NET Web Application Security.

> **Note** You can create a new counter category in Server Explorer by right-clicking the Performance Counters node and choosing the appropriate menu command. You can also edit an existing category by right-clicking its specific node.
>
> **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

For more information, see Introduction to Server Explorer.

Restrictions

In this release, you may have to restart the Performance Monitor (Perfmon.exe) that is installed with Windows 2000 when you create custom performance counters before you can see the custom counter in that application.

The **PerformanceCounter** class is not fully supported on Microsoft Windows NT version 4.0. You can read from the system counters, but you cannot create, write to, or delete custom counters.

Performance Counter Data Analysis | Performance Counter Programming Architecture | Performance Counter Lifetime | Performance Counter Types

Performance Counter Data Analysis

Analyzing performance counter data consists of examining counter values that are reported while your system is performing various operations. During this analysis you could determine which processes are most active and which programs or threads, if any, are monopolizing a resource. Using this type of performance data analysis, you can understand how your system is responding to workload demands.

As a result of this analysis, you might find that your system performs satisfactorily at times and unsatisfactorily at others. Depending on the causes of these variations and the degree of difference, you might choose to take corrective action or to accept these variations and delay tuning or upgrading resources to a later time.

The level of system performance that you consider acceptable when your system is handling a typical workload and running all required services is its baseline. The baseline performance is a subjective standard that the administrator determines based on the work environment. It might correspond to a range of counter values, including some that are temporarily unacceptable, but which generally indicate the best possible performance under the administrator's specific conditions.

Determining Acceptable Values for Counters

A large set of factors determines the normal operating range for each counter in a typical system. You must drive your system through a large number of conditions and develop a sense for normal operating ranges for your equipment. You should record these typical values in log files for future reference. Then, as you make changes to your workload or your hardware, you can refer to your earlier experience as a baseline.

In general, deciding whether or not performance values are acceptable is a subjective judgment that varies significantly with variations in user environments. The values you establish as the baseline for your organization are the best basis for comparison. You should stress test your applications before releasing them and determine the performance thresholds that cause problems. After releasing the application to a live site, you can monitor the performance and take appropriate action if these thresholds are reached.

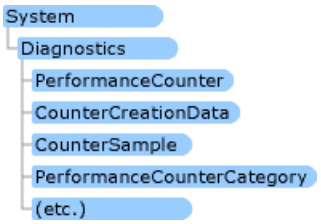
Performance Counter Programming Architecture

The **PerformanceCounter** component uses these portions of the Microsoft .NET Framework namespaces:

PerformanceCounter Namespace



When you add an instance of the **PerformanceCounter** component to your application, Visual Studio .NET automatically creates the references and import statements you need to access the namespace and classes. However, if you are creating your **PerformanceCounter** instances in code, you might need to create a reference to the System.Diagnostics namespace and add a statement to your project importing (in Visual Basic) or using (in C#) the appropriate namespace.

For more information on adding and removing project references, see Adding and Removing References.

Key Performance Counter Classes

The following are the major classes associated with **PerformanceCounter** components:

- **System.Diagnostics.**PerformanceCounter — the base class used to create **PerformanceCounter** components and interact with their values.
- **System.Diagnostics.**PerformanceCounterCategory — provides access to the categories for which performance counters exist on a server and all of their corresponding properties and methods. You use methods in this class to create new categories and custom counters, to verify that categories and counters exist, and to read the existing counters in a category.
- **System.Diagnostics.**CounterCreationData — used to create multiple counters for a category; allows you to explicitly choose the counter type for each counter you create.
- **System.Diagnostics.**InstanceData — used to retrieve multiple instances of a counter and all of their corresponding properties and methods.

Key Programming Elements in the PerformanceCounter and PerformanceCounterCategory Classes

You can use the following methods to interact with performance counters:

- Use the Create method on the PerformanceCounterCategory class to define a new category containing one or more counters. Similarly, the Delete method removes a user-defined category and the counters it contains.
- Use the Exists method on the **PerformanceCounterCategory** class to determine if a category of counters already exists.
- Use the Increment or IncrementBy methods on the PerformanceCounter class to increment a counter value by one or by the specified integer and to return the new value of the counter. Similarly, you can use the Decrement method to reduce a counter's value.
- Use the NextValue method on the **PerformanceCounter** class to return the next calculated value for the sample, or the NextSample method to return the next sampling.
- Use the GetCounters method on the **PerformanceCounterCategory** class to return an array of counters in a category.

Adding and Removing References | Introduction to Monitoring Performance Thresholds

Performance Counter Lifetime

It is important to understand that performance counter values are values rather than entries — when you write a value to a performance counter, you are not making a permanent entry in the counter as you do when you write an entry to an event log. Rather, performance counter values are transitory. When the last **PerformanceCounter** component to reference a particular system counter is disposed of, the counter resets itself to zero.

There are several ways you can manage the lifetime of a performance counter if you want to retain values for a longer period of time than the default counter behavior allows:

- You can run the Performance Monitor application on the server where the counter lives. As long as Performance Monitor is open and actively monitoring the category for your counter, the reference to the counter is maintained and counter values continue to accumulate.
- You can make sure that there is always an instance of the **PerformanceCounter** component connected to the particular counter for which you want to maintain values.

Introduction to Monitoring Performance Thresholds | Performance Counter Types

Performance Counter Types

Performance counters have a type definition that determines how they interact with monitoring applications and the counter values they contain. For example, suppose you are creating an instance of the **PerformanceCounter** component to count the number of orders processed per second in your e-commerce application. You create a performance counter that increments by one after processing each order. In this case, you would set the CounterType to RateOfCountsPerSecond32. This type tells the counter to calculate the number of orders processed per second by taking two samplings and dividing by the timing of the samples. The more samplings taken, the more relevant the data becomes.

Choosing the Right Counter Type

There are many types of performance counters you can choose from when you create a counter. Some of the counters have specific calculations associated with them, and some contain uncalculated values only. In general, there are a few counter types that you will use most frequently. The following table lists these types by common usage patterns.

If You Need To	Use This Type of Counter	Example
Maintain a simple count of items, operations, and so on.	**NumberofItems32**	You might use this counter type to track the number of orders received as a 32-bit number.
Maintain a simple count with a higher capacity	**NumberofItems64**	You might use this counter type to track orders for a site that experiences very high volume; stored as a 64-bit number.
Track the amount per second of an item or operation	**RateOfCountsPerSecond32**	You might use this counter type to track the orders received per second on a retail site; stored as a 32-bit number.
Track the amount per second with a higher capacity	**RateOfCountsPerSecond64**	You might use this counter type to track the orders per second for a site that experiences very high volume; stored as a 64-bit number.
Calculate average time to perform a process or to process an item	**AverageTimer32**	You might use this counter type to calculate the average time an order takes to be processed; stored as a 32-bit number.

A few caveats on counter type:

- Counter type affects whether the Calculate method will work or raise an error. You cannot perform a calculation on counters of type **NumberofItems32**, **NumberofItems64**, **NumberofItemsHEX32**, **NumberofItemsHEX64**, or **RawBase**.
- If you are comparing two samples, they must be of the same counter type. For more information on samples, see Performance Counter Value Retrieval.

For a full list of the types available, see PerformanceCounterType Enumeration.

Creating PerformanceCounter Component Instances

You create an instance of the **PerformanceCounter** component when you want to make available performance data about your application or monitor the performance of resources on your system. **PerformanceCounter** components allow you to connect to existing performance counters, write values to custom counters, and react to values the counters receive.

PerformanceCounter components have no visual user interface. If you add an instance of the **PerformanceCounter** component to a visual designer (such as the Windows Forms Designer), the component appears in a small area below the bottom border of the form. This is known as the component tray and acts as a place to display all of the non-visual items associated with the form.

> **Note** Nonvisual classes that inherit from **System.ComponentModel.Component** support a visual design surface similar to the component tray, on which your **PerformanceCounter** component and other components are arranged. The arrangement of items on this designer is not important, as the interface you see will never be displayed to the application's end users.

There are several ways you can create an instance of the **PerformanceCounter** component:

- You can locate the counter you want in Server Explorer and add it to your designer, creating an instance of the **PerformanceCounter** component that is preconfigured to point to that counter.
- You can drag an instance of the **PerformanceCounter** component from the **Components** tab of the Toolbox to a form or other designer.
- You can create an instance of the **PerformanceCounter** component in code.

To create an instance of the PerformanceCounter components from Server Explorer

1. In Server Explorer, expand the **Servers** node, and then expand the node for the server you want to view.

   > **Note** If the server you want is not listed, you need to add it. For more information, see Accessing and Initializing Server Explorer.

   > **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

2. Locate and expand the **Performance Counters** node beneath it.
3. Locate the counter you want to add to your project, and then right-click it.
4. Click **Add to Designer**.
5. Configure your component. For more information, see Configuring PerformanceCounter Component Instances.

To create an instance of the PerformanceCounter component from the Toolbox

1. Access the **Components** tab of the Toolbox.
2. Select the **PerformanceCounter** icon and drag it to the designer surface for your form or component.
3. Configure your component. For more information, see Configuring PerformanceCounter Component Instances.

To create an instance of the PerformanceCounter component programmatically

1. Create an instance of the **PerformanceCounter** class in code. You code might look like this:

```
' Visual Basic
Dim myCounter As New System.Diagnostics.PerformanceCounter()

// C#
System.Diagnostics.PerformanceCounter myCounter =
   new System.Diagnostics.PerformanceCounter();
```

2. Configure any other necessary properties for your component. For more information, see Configuring PerformanceCounter Component Instances.

See Also

Configuring PerformanceCounter Component Instances | Accessing and Initializing Server Explorer

Configuring PerformanceCounter Component Instances

There are a variety of properties you must set on the **PerformanceCounter** components you create. These determine the counter with which the component interacts. The properties you must set include:

- CategoryName, which determines the performance object with which the component will interact. All performance counters in Windows are grouped by categories, such as Memory, Processes, and Processor.
- CounterName, which identifies the counter within the specified category with which the component will interact.
- InstanceName, which identifies the instance of the category with which the component will interact. Note that many categories do not contain instances, so this property might be left blank, indicating a single instance counter.

  > **Note** If the Category has been set to a category that was not defined by the user, you must choose from existing counters and instances. You can only create new counters and instances in custom categories. For example, you cannot create a new counter in the Memory category, but if you create a new category called Orders, you can define as many counters and instances as you need within that category.

- MachineName, which identifies the server on which the performance counter with which you want your component to interact resides. You can set this property to "." to indicate the local machine or leave it blank to default to this value.
- ReadOnly, which determines whether any custom counter you create can be written to. By default, any **PerformanceCounter** component instances you configure to work with existing Windows counters function in read-only mode and will not allow you to change values in these counters. When you configure your component instance to work with a custom counter, however, you have a choice to accept the default of working in read-only mode, or resetting the property value to **false** to allow values to be written.

  > **Note** You can write counters only on the local machine. If you intend to read counter values, you can choose any computer to which you have access.

To configure an instance of the PerformanceCounter component

1. Create an instance of the **PerformanceCounter** component. For more information, see Creating PerformanceCounter Component Instances.
2. Indicate the counter with which your component should interact by setting the following properties.

Property	Setting
MachineName	Any server to which you have access.
CategoryName	Any category that exists on the server.
CounterName	Any counter within the selected category.

3. If the counter with which you are interacting has several instances, set the appropriate one as the value of the **InstanceName** property.
4. If you are working with a custom counter and want write access, set the **ReadOnly** property to **false**.

   > **Note** You can specify these properties either in the Properties window, in code, or by using special forms of the constructor for the **PerformanceCounter** component instance.

   The following example shows how you would set these values programmatically to connect to an existing Windows performance counter called "aborted transactions" on the local server.

```
' Visual Basic
' Connect to an existing Windows counter and category
Dim abortedTransactions As New PerformanceCounter()
abortedTransactions.CategoryName = _
   "distributed transaction coordinator"
abortedTransactions.CounterName = "aborted transactions"
abortedTransactions.MachineName = "."
' Connect to a custom counter and category in writable mode
PerformanceCounterCategory.Create("orders", "desc", "milk", "desc")
Dim myCounter2 As New PerformanceCounter("orders", "milk", False)

// C#
// Connect to an existing Windows counter and category
```

```
System.Diagnostics.PerformanceCounter abortedTransactions =
   new System.Diagnostics.PerformanceCounter();
abortedTransactions.CategoryName =
   "distributed transaction coordinator";
abortedTransactions.CounterName = "aborted transactions";
abortedTransactions.MachineName = ".";
// Connect to a custom counter and category in writable mode
System.Diagnostics.PerformanceCounterCategory.Create(
   "orders", "desc", "milk", "desc");
System.Diagnostics.PerformanceCounter myCounter2 =
   new System.Diagnostics.PerformanceCounter("orders", "milk", false);
```

Note In this code, "." represents the local machine.

Creating PerformanceCounter Component Instances | Creating Custom Performance Counters | Category and Counter Management

Category and Counter Management

You create categories and custom performance counters if you want to track data that is not captured by the standard counters provided with Microsoft Windows. For example, you might create a custom counter to track the total number of users logged on to your Web site, or to track the orders processed per second by your site. When you create a counter, you add it to a performance counter category, and you assign it a type that governs how it will behave. For information on choosing the correct type, see Performance Counter Types.

There are several ways you can create custom counters:

- You can create a single counter within a category using the Create method on the **PerformanceCounter** class. For more information, see Creating Performance Counter Categories.
- You can create multiple counters within a single category using the CounterCreationData class. For more information, see Creating Custom Performance Counters.

You must create counters in a user-defined category rather than in the performance objects (called categories in Visual Studio .NET and the .NET Framework) defined by Windows. That is, you cannot create a new counter within the Processor category or any other system-defined categories. Additionally, you must create a counter in a new category; adding a counter to an existing user-defined category will raise an exception.

The following restrictions apply to the process of creating new counters:

- You can create custom counters on the local computer, provided that you have administrator access.
- If you do not specify a counter type when creating the counter and its category, it will default to NumberofItems32.
- You cannot create new counters within existing categories. If you need to add counters to categories that already exist, the only way you can do so is to delete the category and recreate it with all of its contents, including the new counters you want to add.
- There are security restrictions that affect your ability to create counters and categories. For more information, see Introduction to Monitoring Performance Thresholds.
- The **PerformanceCounter** class is not fully supported on Microsoft Windows NT version 4.0. You can read from the system counters, but you cannot create, write to, or delete custom counters.

See Also

Creating Custom Performance Counters | Creating Performance Counter Categories | Deleting Performance Counter Categories | Determining If Counters and Categories Exist | Adding and Removing Performance Counter Instances | Performance Counter Types

Creating Custom Performance Counters

When you create a new counter, you first create a category, and then specify one or more counters to be placed in it. You can do this in one of the following ways:

- You can use Server Explorer to create one or more counters at design time.
- You can use the CounterCreationData class to create one or more counters programmatically, then add them to a collection of type CounterCreationDataCollection and pass the collection as a parameter of a special form of the Create method.
- You can use the **Create** method on the **PerformanceCounterCategory** class to create a single counter within a new category. For more information, see Creating Performance Counter Categories.

There are two special issues to be aware of when creating counters and categories. First, you cannot create custom categories and counters on remote machines. Second, your interaction with custom counters and categories is restricted to read-only mode unless you explicitly specify otherwise. In read-only mode, you cannot increment or decrement them or set the raw value or other values within them. You can use the **ReadOnly** property to set a custom counter to writable mode.

It is important to note the difference between creating a counter and creating an instance of the **PerformanceCounter** component. When you create a counter, you are creating a new category and its associated counters in the Windows operating system, rather than a component in your project or application. When you create an instance of the **PerformanceCounter** component, you create a component inside your Visual Studio .NET project that references an external counter.

> **Note** There are security restrictions that affect your ability to use performance counters. For more information, see Introduction to Monitoring Performance Thresholds.
>
> **Security Note** When you create a performance counter, be aware that the resource may already exist. Another process, perhaps a malicious one, may have already created the resource and have access to it. When you put data in the performance counter, the data is available to the other process.
>
> **Note** The **PerformanceCounter** class is not fully supported on Microsoft Windows NT version 4.0. You can read from the system counters, but you cannot create, write to, or delete custom counters.

To create a new category and custom performance counter at design time

1. Open Server Explorer and expand the node for the server you want to view.

   > **Note** If the server you want is not listed, you need to add it. For more information, see Accessing and Initializing Server Explorer.
   >
   > **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

2. Right-click the **Performance Counters** node and select **Create New Category**.

   The Performance Counter Builder dialog box appears.

3. Enter a name and description for the category you want to create.

   > **Note** If you specify the name of an existing category, an error will be raised. To overwrite an existing counter category, you must first delete the category using the **Delete** method, and then add a new category.

4. In the **New Counter** frame, do the following:
   a. Specify a name for the counter you want to create within the category.
   b. Choose a type from the **Type** drop-down list.
   c. Enter a description for the counter.
5. Click **Add to List**.
6. Repeat steps 4 and 5 for each counter you want to create in this category.

   > **Tip** Before you exit the dialog box, you can select any of the counters in the Counters list and edit their values, or delete the counters.
   >
   > **Note** Counters and categories you create in the dialog box are read-write enabled by default, but your interaction with them via an instance of the **PerformanceCounter** component will be restricted to read-only unless you specify otherwise.

To create a new category and set of performance counters programmatically

1. Create a collection of type CounterCreationDataCollection.
2. Create the counters you want to create as objects of type CounterCreationData and set their necessary properties.
3. Add the **CounterCreationData** objects to the collection by calling the collection's Add method.
4. Call the Create method on the **PerformanceCounterCategory** class and pass the collection to it.

   The following example shows how to create a series of counters and pass them to the category when you create it:

```
' Visual Basic
' Create a collection of type CounterCreationDataCollection.
Dim CounterDatas As New CounterCreationDataCollection()
' Create the counters and set their properties.
Dim cdCounter1 As New CounterCreationData()
Dim cdCounter2 As New CounterCreationData()
cdCounter1.CounterName = "MyCounter1"
cdCounter1.CounterHelp = "help string"
cdCounter1.CounterType = PerformanceCounterType.NumberOfItems64
cdCounter2.CounterName = "MyCounter2"
cdCounter2.CounterHelp = "help string 2"
cdCounter2.CounterType = PerformanceCounterType.NumberOfItems64
' Add both counters to the collection.
CounterDatas.Add(cdCounter1)
CounterDatas.Add(cdCounter2)
' Create the category and pass the collection to it.
PerformanceCounterCategory.Create( _
   "Multi Counter Category", "Category help", CounterDatas)

// C#
// Create a collection of type CounterCreationDataCollection.
System.Diagnostics.CounterCreationDataCollection CounterDatas =
   new System.Diagnostics.CounterCreationDataCollection();
// Create the counters and set their properties.
System.Diagnostics.CounterCreationData cdCounter1 =
   new System.Diagnostics.CounterCreationData();
System.Diagnostics.CounterCreationData cdCounter2 =
   new System.Diagnostics.CounterCreationData();
cdCounter1.CounterName = "Counter1";
cdCounter1.CounterHelp = "help string1";
cdCounter1.CounterType = System.Diagnostics.PerformanceCounterType.NumberOfItems64;
cdCounter2.CounterName = "Counter2";
cdCounter2.CounterHelp = "help string 2";
cdCounter2.CounterType = System.Diagnostics.PerformanceCounterType.NumberOfItems64;
// Add both counters to the collection.
CounterDatas.Add(cdCounter1);
CounterDatas.Add(cdCounter2);
// Create the category and pass the collection to it.
System.Diagnostics.PerformanceCounterCategory.Create(
   "Multi Counter Category", "Category help", CounterDatas);
```

Accessing and Initializing Server Explorer | Creating Performance Counter Categories | Category and Counter Management

Creating Performance Counter Categories

You can create a new category to contain custom counters. For example, if you plan to create a series of counters to track various data about the orders processed on your Web site, you might create a category called OrderData on your server and then create the counters you need within it.

Creating a category is not a distinct process from creating the counters that are placed within it; counters can only be created at the point when you create the category itself. You cannot create categories and counters on or remove them from remote computers.

There are several ways you can create counters and categories:

- You can use the Create method on the PerformanceCounterCategory class to create a new category and simultaneously create a single performance counter within it.
- You can create an array of CounterCreationData objects and pass the array as a parameter of the **Create** methods, creating a set of counters within the category. For more information on this approach, see Creating Custom Performance Counters.
- You can use the Performance Counter dialog box, launched from Server Explorer, to create multiple counters while simultaneously creating a new category. For more information on this approach, see Creating Custom Performance Counters.

> **Note** There are security restrictions that affect your ability to use performance counters. For more information, see Introduction to Monitoring Performance Thresholds.

> **Note** The **PerformanceCounter** class is not fully supported on Microsoft Windows NT version 4.0. You can read from the system counters, but you cannot create, write to, or delete custom counters.

To create a category and a single counter within it

- Call the **Create** method on the **PerformanceCounterCategory** class and specify the following parameters:

Parameter	Value
CategoryName	Any category name that is not already in use on this server.
CategoryHelp	A description of the category.
CounterName	A name for the counter.
CounterHelp	A description of the counter. This text is displayed in Windows Performance Monitor when a user selects a counter and clicks the **Explain** button.

The following example shows how you might create a simple category with the **Create** method:

```
' Visual Basic
Sub CreateCustomCounter()
   PerformanceCounterCategory.Create("MyCategory", "Desc", _
      "MyCounter", "Counterdesc")
End Sub

// C#
void CreateCustomCounter()
{
   System.Diagnostics.PerformanceCounterCategory.Create(
      "MyCategory", "Desc", "MyCounter", "Counterdesc");
}
```

> **Note** By default, the counters created with this code will be read-write enabled, but your interaction with them via a **PerformanceCounter** component instance will be read-only unless you specify otherwise. You can change the value of the **ReadOnly** property for a component instance to **false** if you want to make modifications to a counter.

See Also

Deleting Performance Counter Categories

You can delete performance counter categories when they are no longer needed. You can only delete categories that are not Windows-standard performance objects; that is, you can only delete categories that have been user-defined. In addition, you cannot create or delete categories on remote computers. You might delete a category if you have created a custom category associated with an application and you are removing that application from the system. For example, if you have an order entry application that creates counters in an OrderProcessing category, you would delete that category as part of uninstalling your application.

You use the Delete method on the PerformanceCounterCategory class to remove a category from the system. When you delete a category, all of the counters and instances associated with it are also removed.

It is important to note the difference between deleting a counter and deleting an instance of the **PerformanceCounter** component. When you use the **Delete** method, you are deleting a category and its associated counters from the Windows operating system, rather than removing an instance of a counter from your project or application. When you delete an instance of the **PerformanceCounter** component, you remove a component inside your project that references an external counter.

> **Note** The **PerformanceCounter** class is not fully supported on Microsoft Windows NT version 4.0. You can read from the system counters, but you cannot create, write to, or delete custom counters.

To delete a performance counter category from Server Explorer

1. In Server Explorer, locate the performance counter category you want to remove. For more information, see Accessing and Initializing Server Explorer.

   > **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

2. Right-click the category and select **Delete**.

To delete a performance counter category programmatically

- Call the **Delete** method on the **PerformanceCounterCategory** class, specifying the category to remove as a parameter.

See Also

Category and Counter Management | Adding and Removing Performance Counter Instances

Determining If Counters and Categories Exist

You can use the CounterExists method on the **PerformanceCounterCategory** class to determine if a given performance counter exists within a particular category on either the local or a remote computer. You might do this before creating a new counter to prevent an error from occurring if another counter with that name exists.

In addition to determining whether counters exist, you can determine whether a given category exists by using the Exists method on the **PerformanceCounterCategory** class. You might do this if you are creating a custom counter and want to determine if the category for it already exists. The **Create** method will raise an error if the category you specify has already been created.

Both the **Exists** and the **CounterExists** methods return **true** if the item is found and **false** if it is not.

To determine if a counter exists

- Call the **CounterExists** method on the **PerformanceCounterCategory** class, specifying the following parameters.

Parameter	Value
CounterName	The name of the counter you want to query.
CategoryName	Any category of performance objects on the server.
MachineName	The server on which to locate the category and counter.

  Note In Visual Basic, the **MachineName** parameter is optional; if left blank it defaults to the local machine. In C#, you can use an overload of the **CounterExists** method if you do not want to specify the machine name.

To determine if a category exists

- Call the **Exists** method on the **PerformanceCounterCategory** class, specifying the following parameters.

Parameter	Value
CategoryName	Any category you want to query.
MachineName	The server on which to locate the category.

  The following example shows how to use an **If** statement to determine whether a category exists before creating a category and counter:

```
' Visual Basic
If Not (PerformanceCounterCategory.Exists("MyCat")) Then
   PerformanceCounterCategory.Create( _
      "MyCat", "Description", "MyCounter", "Description")
End If

// C#
if (!System.Diagnostics.PerformanceCounterCategory.Exists("MyCat"))
{
   System.Diagnostics.PerformanceCounterCategory.Create(
      "MyCat", "Description", "MyCounter", "Description");
}
```

Category and Counter Management | Writing Values to Performance Counters | Performance Counter Value Retrieval

Adding and Removing Performance Counter Instances

You can add and remove instances dynamically as you work with counters and categories. For example, you might add an instance for each user of your Web-based retail application so that you could track information about their actions, and then remove the instance when the user's session expires.

You add instances by setting a raw value for a counter. If no instance exists for the counter, an instance is created the first time you set the **RawValue** property, and all subsequent actions on the raw value are assumed to impact that instance if no other is specified. You can create additional instances by specifying a new instance name and then setting a value after it.

> **Note** The process of setting the instance's value, rather than specifying the name of a new instance, creates the instance.

Unlike counters, which cannot be added to an existing category except as part of category creation, instances can be added to and removed from user-defined categories at any time. You can use the **Instance** property to switch between one instance and another.

You can use the RemoveInstance method to remove an instance of a custom performance counter from memory. For example, suppose you have a Web-based retail application that uses a category called OrderInProgress, and within that you maintain instances for each user's current shopping cart. When a user first adds an item to their cart, your application creates a new instance for that user. When the user completes the order, your application deletes the instance. During the order, you update the instance with counters such as NumberofItemsinCart, TimeSinceCreation, and NumberofItemsAddedPerSecond.

You cannot remove instances from the performance counters that are a default part of Windows. If your **PerformanceCounter** component does not refer to a valid instance, this method will throw an exception.

> **Note** The **PerformanceCounter** class is not fully supported on Microsoft Windows NT version 4.0. You can read from the system counters, but you cannot create, write to, or delete custom counters.

To add a performance counter instance

1. Create your categories and counters normally. For more information, see Creating Performance Counter Categories.
2. Set the **Instance** property to a unique name for the instance, and then set the instance's RawValue property.

   The following code shows how to create several instances of an existing performance counter category:

```
' Visual Basic
' Assumes the category and counter have already been created.
Dim myCounter As New System.Diagnostics.PerformanceCounter( _
   "cat", "counter", "instance1", False)
' Set the raw value to automatically create instance1.
myCounter.RawValue = 100
' State that you will now be working with a different instance.
myCounter.InstanceName = "instance2"
' Setting the value actually creates instance2.
myCounter.RawValue = 200

// C#
// Assumes category and counter have been created.
System.Diagnostics.PerformanceCounter myCounter =
   new System.Diagnostics.PerformanceCounter(
   "cat","counter","instance1", false);
// Set the raw value to automatically create instance1.
myCounter.RawValue = 100;
// State that you will now be working with a different instance.
myCounter.InstanceName = "instance2";
// Setting the value actually creates instance2.
myCounter.RawValue = 200;
```

To remove a performance counter instance

1. Create an instance of the **PerformanceCounter** component that is connected to the counter from which you want to

remove an instance. For more information, see Creating PerformanceCounter Component Instances.

2. Set the InstanceName property to the instance you want to delete.
3. Call the **RemoveInstance** method on your component.

   The following example shows how to remove an instance called Reference from a counter:

```
' Visual Basic
' Assumes that you have configured PerformanceCounter1 to
' interact with the appropriate counter.
PerformanceCounter1.InstanceName = "Reference"
PerformanceCounter1.RemoveInstance()

// C#
// Assumes that you have configured PerformanceCounter1 to
// interact with the appropriate counter.
PerformanceCounter1.InstanceName = "Reference";
PerformanceCounter1.RemoveInstance();
```

See Also

Creating PerformanceCounter Component Instances | Category and Counter Management

Writing Values to Performance Counters

You write a value to a counter by incrementing the counter's current raw value by a positive or negative number. You do this using the **IncrementBy** method on the **PerformanceCounter** class.

> **Note** Incrementing by a negative number decrements the counter by the absolute value of the number. For example, incrementing with a value of 3 will increase the counter's raw value by three. Incrementing with a value of –3 will decrease the counter's raw value by three.

In addition, you can use the **Increment** and **Decrement** methods to increase or decrease a counter's values by one. These methods are processed much more quickly than **IncrementBy**.

You can only increment values on custom counters; by default, your interactions with system counters via a **PerformanceCounter** component instance are restricted to read-only mode. Before you can increment a custom counter, you must set the **ReadOnly** property on the component instance with which you are accessing it to **false**.

> **Note** There are security restrictions that affect your ability to use performance counters. For more information, see Introduction to Monitoring Performance Thresholds.

> **Note** The **PerformanceCounter** class is not fully supported on Microsoft Windows NT version 4.0. You can read from the system counters, but you cannot create, write to, or delete custom counters.

To write values to performance counters

1. Create a **PerformanceCounter** instance and configure it to interact with the desired category and counter. For more information, see Creating PerformanceCounter Component Instances or Configuring PerformanceCounter Component Instances.
2. Write the value using one of the following methods:

To	Call this method	Parameter
Increase the raw value by one	Increment	None
Decrease the raw value by one	Decrement	None
Increase the raw value by greater than one	IncrementBy	A positive integer
Decrease the raw value by greater than one	IncrementBy	A negative integer
Reset the raw value to any integer, rather than incrementing it	RawValue	A positive or negative integer

The following code shows how to set values for a counter in various ways. This code assumes that you are working on a Windows Form that contains a text box named txtValue and three buttons: one that increments the raw value by the number entered in the text box, one that decrements the raw value by one, and one that sets the raw value of the counter to the value set in the text box.

```
' Visual Basic
Private Sub btnIncrement_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles btnIncrement.Click
   PerformanceCounter1.ReadOnly = False
   PerformanceCounter1.IncrementBy(CLng(txtValue.Text))
End Sub

Private Sub btnDecrement_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles btnDecrement.Click
   PerformanceCounter1.ReadOnly = False
   PerformanceCounter1.Decrement()
End Sub

Private Sub btnSetValue_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles btnSetValue.Click
   PerformanceCounter1.ReadOnly = False
   PerformanceCounter1.RawValue = CLng(txtValue.Text)
End Sub

// C#
```

```
protected void btnIncrement_Click(System.Object sender,
   System.EventArgs e)
{
   performanceCounter1.ReadOnly = false;
   performanceCounter1.IncrementBy(long.Parse(txtValue.Text));
}

protected void btnDecrement_Click(System.Object sender,
   System.EventArgs e)
{
   performanceCounter1.ReadOnly = false;
   performanceCounter1.Decrement();
}

protected void btnSetValue_Click(System.Object sender,
   System.EventArgs e)
{
   performanceCounter1.ReadOnly = false;
   performanceCounter1.RawValue = long.Parse(txtValue.Text);
}
```

Introduction to Monitoring Performance Thresholds | Performance Counter Value Retrieval

Performance Counter Value Retrieval

There are several ways you can read performance counter values:

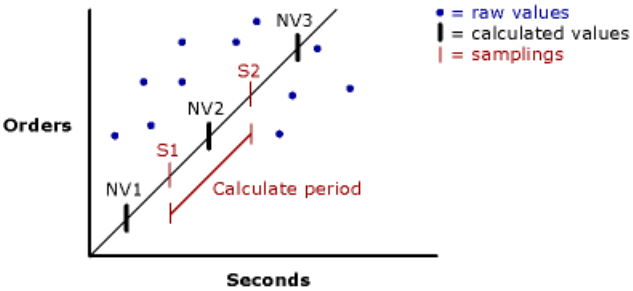
- You can retrieve a raw value from a counter using the RawValue property on the **PerformanceCounter** class.
- You can retrieve the current calculated value for a counter using the NextValue method on the **PerformanceCounter** class.
- You can retrieve a set of samples using the NextSample method on the **PerformanceCounter** class, and compare their values using the CounterSample.Calculate method.

> **Note** There are security restrictions that affect your ability to use performance counters. For more information, see Introduction to Monitoring Performance Thresholds.

Raw, Calculated, and Sampled Data

The interaction between raw values, next (or calculated) values, and samples is fairly straightforward once you understand that raw and calculated values shift constantly, whereas samples allow you to retrieve a static snapshot of the counter at a particular point in time. The following diagram illustrates the relationship between raw value, next value, and samples.

Performance Counter Values: Raw, Calculated, and Sampled



This picture shows a representation of the data contained in a counter called Orders Per Second. The raw values for this counter are individual data points that vary by second, where the calculated average is represented by the line showing an increasing order receipt over time. In this chart, the following data points have been taken:

- The user has used the **NextValue** method to retrieve the calculated value at three different times, represented by NV1, NV2, and NV3. Because the next value is constantly changing, a different value is retrieved each time without specifying any additional parameters.
- The user has used the **NextSample** method to take two samples, indicated by S1 and S2. Samples freeze a value in time, so the user can then compare the two sample values and perform calculations on them.

Comparing Retrieval Methods

Retrieving a raw value with the **RawValue** property is very quick, because no calculations or comparisons are performed. For example, if you are using a counter simply to count the number of orders processed in a system, you can retrieve the counter's raw value. For more information on retrieving raw values, see Retrieving Raw Performance Counter Values.

Retrieving a calculated value with the **NextValue** method is often more useful than retrieving the raw value, but this value may also give you an unrealistic view of the data because it can reflect unusual fluctuations in the data at the moment when the value is calculated. For example, if you have a counter that calculates the orders processed per second, an unusually high or low amount of orders processed at one particular moment will result in an average that is not realistic over time. This may provide a distorted view of the actual performance of your system. For more information on retrieving a calculated value, see Retrieving Calculated Performance Counter Values.

Samples provide the most realistic views of the data in your system by allowing you to retrieve, retain, and compare various values over time. You would retrieve a sample, using the **NextSample** method, if you needed to compare values in different counters or calculate a value based on raw data. This may be slightly more resource-intensive, however, than a **NextValue** call. For more information on retrieving a sample, see Retrieving Performance Counter Samples.

The **NextSample** method returns an object of type CounterSample. When you retrieve a sample, you have access to properties on the **CounterSample** class such as **RawValue**, **BaseValue**, **TimeStamp**, and **SystemFrequency**. These properties let you get a very detailed look at the data that makes up the sample data.

Retrieving Raw Performance Counter Values | Retrieving Calculated Performance Counter Values | Retrieving Performance Counter Samples | Retrieving Lists of Counters and Categories | Introduction to Monitoring Performance Thresholds

Retrieving Raw Performance Counter Values

You retrieve raw performance counter values by retrieving the current value of the **RawValue** property on the **PerformanceCounter** class.

To retrieve a counter's raw value

1. Create a **PerformanceCounter** instance and configure it to interact with the desired category and counter. For more information, see Creating PerformanceCounter Component Instances or Configuring PerformanceCounter Component Instances.
2. Retrieve the current value of the **RawValue** property.

   The following example illustrates how to use the **RawValue** property to retrieve the current value of the % Processor Time counter:

```
' Visual Basic
Dim MyCounter As New PerformanceCounter()
MyCounter.CategoryName = "Processor"
MyCounter.CounterName = "% Processor Time"
MyCounter.InstanceName = "_Total"
Dim raw As Int64
raw = MyCounter.RawValue

// C#
System.Diagnostics.PerformanceCounter myCounter =
   new System.Diagnostics.PerformanceCounter();
myCounter.CategoryName = "Processor";
myCounter.CounterName = "% Processor Time";
myCounter.InstanceName = "_Total";
long raw = myCounter.RawValue;
```

See Also

Performance Counter Value Retrieval | Retrieving Calculated Performance Counter Values | Retrieving Performance Counter Samples | Retrieving Lists of Counters and Categories

Retrieving Calculated Performance Counter Values

You retrieve calculated performance counter values by calling the NextValue method on the current counter. The counter's calculated value at the instant that the method executes is calculated and returned to you. Calling **NextValue** a second time will retrieve a different value, because the calculated value changes as the counter increments.

> **Note** To retrieve more complex views of the data in the counter, you can use samples to retrieve static snapshots of counter data at two points in time, and perform comparisons on those returns. For more information on retrieving a sample, see Retrieving Performance Counter Samples.

To retrieve a counter's calculated value

1. Create a **PerformanceCounter** instance and configure it to interact with the desired category and counter. For more information, see Creating PerformanceCounter Component Instances or Configuring PerformanceCounter Component Instances.
2. Call the **NextValue** method and set the results to an integer variable.

   The following example illustrates how to use the **NextValue** property to retrieve the current value of the Total counter in a custom category called Orders:

```
' Visual Basic
Dim MyCtr As New PerformanceCounter()
MyCtr.CategoryName = "Orders"
MyCtr.CounterName = "Total"
Dim retvalue As Single
retvalue = MyCtr.NextValue()

// C#
System.Diagnostics.PerformanceCounter MyCtr =
   new System.Diagnostics.PerformanceCounter();
MyCtr.CategoryName= "Orders";
MyCtr.CounterName= "Total";
float retvalue = MyCtr.NextValue();
```

> **Note** The first time you run this code, it will return zero. Subsequent queries for the value will return a figure.

Performance Counter Value Retrieval | Retrieving Performance Counter Samples | Creating PerformanceCounter Component Instances | Configuring PerformanceCounter Component Instances

Retrieving Performance Counter Samples

You use the CounterSample class to create samples and perform calculations on their contents. A sample class performs a "sampling" of a performance counter based on criteria you define. These criteria include the values from one or more counters and the frequency with which values should be provided. In addition, the class records the time at which samples were taken. You can collect all of this data in a single instantiated class and then use the Calculate method to perform a calculation. You can also use the **Calculate** method to perform a calculation that compares values in two different samples.

The calculation performed depends on the type of the counters; certain counter types have specific calculations associated with them. For example, counters of the type **ElapsedTime** compare the time stamp on two different samples and determine how much time has elapsed. Many counters perform an averaging calculation based on the data retrieved.

These are the steps you go through to define a sample:

- Create one or more instances of the **CounterSample** class.
- Retrieve a current sample for each instance.
- Call the **Calculate** method, passing each sample to be included in the calculation as a parameter.

To retrieve performance counter samples and perform a calculation

1. Create a **PerformanceCounter** instance and configure it to interact with the desired category and counter. For more information, see Creating PerformanceCounter Component Instances or Configuring PerformanceCounter Component Instances.
2. Create an instance of the **CounterSample** class to hold the results of the sampling.
3. Call the **NextSample** method on the **PerformanceCounter** component instance to retrieve the calculated value, and assign the result to the **CounterSample** class.

   Tip You must retrieve two samples to perform a calculation.

4. Create a variable to hold the results of the calculation, and give it a data type of Single .
5. For each of the two samples that you need for your calculation, assign a return value of **NextSample** to a variable of type **CounterSample**.
6. Call the **Calculate** method on the **CounterSample** class, and do one of two things:

   - If you have retrieved two samples, pass both of the samples (which are stored as **CounterSample** objects) to the **Calculate** method as parameters.

     - or -

   - If you have retrieved only one sample, pass the first sample to the **Calculate** method, and then use the second parameter to retrieve another sample.

7. Set the result of the calculation equal to the variable you created to contain the result.

   Note The two samples must be from counters of the same type or the method will throw an exception. The type of counter determines what kind of calculation performed. For more information, see Performance Counter Types.

The following code illustrates how to retrieve two samples and compare them using the **Calculate** method:

```
' Visual Basic
' Dim variables of types CounterSample for each sample and a
' variable of type single for the results.
Dim sample1 As CounterSample
Dim sample2 As CounterSample
Dim result As Single
' Retrieve a sample.
sample1 = PerformanceCounter1.NextSample()
' Wait some interval of time here and retrieve
' a second sample.
System.Threading.Thread.Sleep(1000)
sample2 = PerformanceCounter1.NextSample()
```

```
' Pass both samples to the Calculate method.
result = CounterSample.Calculate(sample1, sample2)

// C#
System.Diagnostics.CounterSample sample1;
System.Diagnostics.CounterSample sample2;
float result;
// Retrieve a sample.
sample1 = PerformanceCounter1.NextSample();
// Wait some interval of time here and retrieve
// a second sample.
System.Threading.Thread.Sleep(1000);
sample2 = PerformanceCounter1.NextSample();
// Pass both samples to the Calculate method.
result = System.Diagnostics.CounterSample.Calculate(sample1, sample2);
```

Alternatively, you can call the **NextSample** method to provide the values for the second sample. The following example illustrates using this approach:

```
' Visual Basic
Dim sample1 As CounterSample
Dim result As Single
' Retrieve a single sample.
sample1 = PerformanceCounter1.NextSample()
' Pass the retrieved sample to the calculate method
' and retrieve another sample in the second parameter.
result = CounterSample.Calculate(sample1, PerformanceCounter1.NextSample())

// C#
System.Diagnostics.CounterSample sample1;
float result;
// Retrieve a single sample.
sample1 = PerformanceCounter1.NextSample();
// Pass the retrieved sample to the calculate method
// and retrieve another sample in the second parameter.
result = System.Diagnostics.CounterSample.Calculate(sample1, PerformanceCounter1.NextSamp
le());
```

Performance Counter Value Retrieval | Retrieving Raw Performance Counter Values | Retrieving Calculated Performance Counter Values | Retrieving Lists of Counters and Categories

Retrieving Lists of Counters and Categories

You can use the GetCounters method on the PerformanceCounterCategory class to quickly retrieve a list of all of the counters or instances in a specific category. Each time you request a value from a category by creating an instance of a **PerformanceCounter** object, setting it to an existing counter, and retrieving a value, the system reads through the entire category and retrieves the requested counter. This means that if you request five different counters from a category that contains 20 counters, the system reads all 20 counters in the category five times, searching for each counter separately. Using **GetCounters**, you get the same data, but the category is read only once.

The **GetCounters** method returns an array of type **PerformanceCounter** that contains the counters in the category. You can use the **Item** property to work with the contents of the collection.

In addition to retrieving counters, you can also use the static GetCategories method to return a list of categories on the current computer or any server to which you have access. **GetCategories** returns an array of **PerformanceCounterCategories** objects.

To retrieve the counters in a category

1. Create a **PerformanceCounter** object and configure it so that it points to the desired category. For more information, see Creating PerformanceCounter Component Instances or Configuring PerformanceCounter Component Instances.
2. Create an array of type **PerformanceCounter** to contain the resulting category list.
3. Call the **GetCounters** method on the **PerformanceCounterCategory** class and specify the desired category as a parameter.
4. Set the results to the array.

   The following example shows how to retrieve all of the counters in the **Cache** category. This code assumes that you are working in a Windows Form that contains a button and a **ListBox** control. It also assumes that you have a reference to the **Systems.Diagnostics** namespace and an **imports** statement (for Visual Basic) or a **using** statement (for C#) to the same:

```
' Visual Basic
Private Sub btnGetCounters_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles btnGetCounters.Click
   Dim mypc() As PerformanceCounter
   Dim i As Integer
   Dim myCat As New PerformanceCounterCategory("Cache")
   ' Remove the current contents of the list.
   Me.ListBox1.Items.Clear()
   ' Retrieve the counters.
   mypc = myCat.GetCounters
   ' Add the retrieved counters to the list.
   For i = 0 To mypc.Length - 1
      Me.ListBox1.Items.Add(mypc(i).CounterName)
   Next
End Sub

// C#
private void btnGetCounters_Click(System.Object sender, System.EventArgs e)
{
   System.Diagnostics.PerformanceCounter[] mypc;
   System.Diagnostics.PerformanceCounterCategory mycat =
      new System.Diagnostics.PerformanceCounterCategory("cache");
   // Remove the current contents of the list.
   this.listBox1.Items.Clear();
   // Retrieve the counters.
   mypc = mycat.GetCounters();
   // Add the retrieved counters to the list.
   for (int i = 0; i < mypc.Length; i++)
   {
      this.listBox1.Items.Add(mypc[i].CounterName);
   }
}
```

To retrieve all categories on a machine

1. Create an array of type **PerformanceCounter** to contain the resulting category list.
2. Call the **GetCategories** method on the **PerformanceCounterCategory** class and specify the desired category as a parameter.
3. Set the results to the array.

   The following code shows how to retrieve all categories on the local machine. This code assumes that you are working in a Windows form that contains a button and a **ListBox** control. It also assumes that you have a reference to the **Systems.Diagnostics** namespace and an imports statement (for Visual Basic) or a using statement (for C#) to the same:

```
' Visual Basic
Private Sub btnGetCategories_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs)
   Dim myCat2 As PerformanceCounterCategory()
   Dim i As Integer
   ' Clear the contents of the list box.
   Me.listBox2.Items.Clear()
   ' Retrieve the categories.
   myCat2 = PerformanceCounterCategory.GetCategories
   ' Add the retrieved categories to the list.
   For i = 0 To myCat2.Length - 1
      Me.listBox2.Items.Add(myCat2(i).CategoryName)
   Next
End Sub

// C#
private void btnGetCategories_Click(object sender, System.EventArgs e)
{
   System.Diagnostics.PerformanceCounterCategory[] myCat2;
   // Clear the list's current contents.
   this.listBox2.Items.Clear();
   // Retrieve the categories.
   myCat2 =
      System.Diagnostics.PerformanceCounterCategory.GetCategories();
   // Add the retrieved categories to the list.
   for (int i = 0; i < myCat2.Length; i++)
   {
      this.listBox2.Items.Add(myCat2[i].CategoryName);
   }
}
```

Working with Performance Counters in Server Explorer

Using Server Explorer, you can explore existing performance counters on any computer to which you have access. You can view any counter available on these computers, including those you create in Visual Studio .NET.

> **Note** You can also see information about performance counters in the Windows 2000 Performance window.

> **Note** The Servers node of the Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

The Performance Counters node in Server Explorer lists the categories that exist on each server. You can expand each counter to see the instances it represents. Note that instances apply to the category rather than to individual counters, so each counter within a category will have the same instances.

To locate a performance counter in Server Explorer

1. Expand the **Server** node, and then expand the node for the server you want to view.

   > **Tip** If the server you want to view is not listed, you need to add it. For more information, see Accessing and Initializing Server Explorer.

2. Locate and expand the **Performance Counters** node beneath it.

To locate a performance counter in Windows

1. Access the **Control Panel** for your computer.
2. Double-click **Administrative Tools**, and then double-click **Performance**. The **Performance** console window appears.
3. To add a counter to the display, right-click the graph area in the window and select **Add Counters**.

Walkthrough: Retrieving Categories and Counters

The procedures in this walkthrough take you through the process of creating and configuring **PerformanceCounter** component instances and using them to retrieve lists of performance counter categories and counters on your system. A performance counter is the means by which Windows collects performance data on various system resources. Windows contains a set of predefined counters, organized into categories, with which you can interact. Each category and counter is related to a specific area of system functionality.

In this walkthrough you will:

- Instantiate a **PerformanceCounter** component and configure it to interact with a specific category of system-generated counters.
- Create a Windows Application that displays information about categories and counters in a list box.
- Use the **GetCategories** method to return a list of categories on the local computer.
- Use the **GetCounters** method to return a list of counters from the specified category.

To create your Windows Application

1. From the **New Project** dialog box, create a Visual Basic or C# Windows Application.
2. From the **Windows Forms** tab of the Toolbox, add two buttons and two list boxes to your form. Arrange them in any order you like, and then set the following properties for them:

Control	Property	Value
Button1	Name	**btnGetCounters**
	Text	**Get Counters**
Button2	Name	**btnGetCategories**
	Text	**Get Categories**
ListBox1	Name	**lstCounters**
	ScrollAlwaysVisible	**True**
ListBox2	Name	**lstCategories**
	ScrollAlwaysVisible	**True**

3. Save your work.

To retrieve the category list

1. In Design view, double-click the **Get Categories** button to access the Code Editor. Your cursor will be positioned in the **btnGetCategories_Click** event.
2. In the **btnGetCategories_Click** procedure, add the following code to retrieve the list of categories from the local computer.

```
' Visual Basic
Private Sub btnGetCategories_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles btnGetCategories.Click

   Dim myCat2 As PerformanceCounterCategory()
   Dim i As Integer
   ' Remove the current contents of the list.
   Me.lstCategories.Items.Clear()
   ' Retrieve the categories.
   myCat2 = PerformanceCounterCategory.GetCategories
   ' Add the retrieved categories to the list.
   For i = 0 To myCat2.Length - 1
      Me.lstCategories.Items.Add(myCat2(i).CategoryName)
   Next
End Sub

// C#
private void btnGetCategories_Click(object sender, System.EventArgs e)
{
   System.Diagnostics.PerformanceCounterCategory[] myCat2;
   // Remove the current contents of the list.
```

```
   this.lstCategories.Items.Clear();
   // Retrieve the categories.
   myCat2 =
      System.Diagnostics.PerformanceCounterCategory.GetCategories();
   // Add the retrieved categories to the list.
   for (int i = 0; i < myCat2.Length; i++)
   {
      this.lstCategories.Items.Add(myCat2[i].CategoryName);
   }
}
```

To retrieve the counter list

1. In Design view, double-click the **Get Counters** button to access the Code Editor. The insertion point will be positioned in the **btnGetCounters_Click** event.
2. Add the following code to retrieve the list of counters from the selected category.

```
' Visual Basic
Private Sub btnGetCounters_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles btnGetCounters.Click

   Dim instanceNames() As String
   Dim counters As New System.Collections.ArrayList()

   If (Me.lstCategories.SelectedIndex <> -1) Then
      Dim mycat As New PerformanceCounterCategory( _
         Me.lstCategories.SelectedItem.ToString())
      ' Remove the current contents of the list.
      Me.lstCounters.Items.Clear()
      ' Retrieve the counters.
      Try
         instanceNames = mycat.GetInstanceNames()
         If (instanceNames.Length = 0) Then
            counters.AddRange(mycat.GetCounters())
         Else
            Dim i As Integer
            For i = 0 To instanceNames.Length - 1
               counters.AddRange( _
                  mycat.GetCounters(instanceNames(i)))
            Next
         End If
         ' Add the retrieved counters to the list.
         Dim counter As PerformanceCounter
         For Each counter In counters
            Me.lstCounters.Items.Add(counter.CounterName)
         Next
      Catch ex As Exception
         MessageBox.Show( _
            "Unable to list the counters for this category:" _
            & ControlChars.CrLf & ex.Message)
      End Try
   End If
End Sub

// C#
private void btnGetCounters_Click(object sender, System.EventArgs e)
{
   string[] instanceNames;
   System.Collections.ArrayList counters = new
```

```
        System.Collections.ArrayList();
    if (this.lstCategories.SelectedIndex != -1)
    {
        System.Diagnostics.PerformanceCounterCategory mycat = new
            System.Diagnostics.PerformanceCounterCategory(
            this.lstCategories.SelectedItem.ToString());
        // Remove the current contents of the list.
        this.lstCounters.Items.Clear();
        // Retrieve the counters.
        try
        {
            instanceNames = mycat.GetInstanceNames();
            if (instanceNames.Length == 0)
            {
                counters.AddRange(mycat.GetCounters());
            }
            else
            {
                for (int i = 0; i < instanceNames.Length; i++)
                {
                    counters.AddRange(mycat.GetCounters(instanceNames[i]));
                }
            }

            // Add the retrieved counters to the list.
            foreach (System.Diagnostics.PerformanceCounter counter
                in counters)
            {
                this.lstCounters.Items.Add(counter.CounterName);
            }
        }
        catch (System.Exception ex)
        {
            MessageBox.Show(
                "Unable to list the counters for this category:\n"
                + ex.Message);
        }
    }
}
```

To test your application

1. Save and compile your application.
2. Click the **Get Categories** button. You will see a list of categories in the list box.
3. Select one of the categories and click the **Get Counters** button. You will see a list of the counters for the selected category.

Walkthrough: Changing and Retrieving Performance Counter Values

> **Note** The Servers node of Server Explorer used in this walkthrough is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

The procedures in this walkthrough show you how to work with the values of a performance counter using the methods on the **PerformanceCounter** class. A performance counter is the means by which Windows collects performance data on various system resources. Windows contains a set of pre-defined counters, organized into categories, with which you can interact. The values you retrieve from a counter can either be raw values or calculated values that alter over time. There are several ways to increase and decrease the current value of a counter.

In the course of this walkthrough, you will:

- Create and configure a **PerformanceCounter** component to interact with a system-provided counter.
- Create a Windows application that contains UI elements that retrieve and display values from a counter.
- Write code using the **RawValue** method to both set and retrieve the raw value of the counter.
- Write code using the **Increment**, **IncrementBy**, and **Decrement** methods to alter the value of the counter and retrieve its new value.

To create your Windows Application

1. On the **File** menu, point to **New**, then click **Project**.
2. In the **New Project** dialog box, choose Visual Basic or Visual C# in the left pane, then choose the **Windows Application** template. Name the project **PerformanceCounterExample**.
3. From the **Windows Forms** tab of the Toolbox, add the following controls to your application:
   - Two labels
   - A text box
   - Five buttons
4. Set the following properties on your controls:

Control	Property	Value
Label1	Name	lblCounterValue
	Text	(blank)
Label2	Name	lblSystemCounterValue
	Text	(blank)
Textbox1	Name	txtValue
	Text	(blank)
Button1	Name	btnSetRawValue
	Text	Set Raw Value of the Custom Counter
Button2	Name	btnGetNextValue
	Text	Get Next Value of System Counter
Button3	Name	btnIncrement
	Text	Increase the Custom Counter by 1
Button4	Name	btnDecrement
	Text	Decrease the Custom Counter by 1
Button5	Name	btnIncrementBy
	Text	Increase Custom Counter by a value

5. Arrange the controls as you like.
6. Save your work.

To create and configure your PerformanceCounter component

1. Open Server Explorer and access the **Servers** node. For more information, see Accessing and Initializing Server Explorer.
2. Locate the listing for your computer under the **Servers** node and expand it. You will see entries for performance counters,

messages queues, event logs, and services.

3. Expand the **Performance Counters** node and locate the **Processor** node.
4. Locate the **% Processor Time** node and expand it.
5. Drag the **_Total** counter onto the form. A **PerformanceCounter** component configured for the **_Total** counter is added to your project. The component is named **PerformanceCounter1** in Visual Basic, and **performanceCounter1** in Visual C#.

To retrieve the raw value of the system counter

1. In the designer, double-click the **Get Next Value** button to create the **Click** event handler. This method will report the calculated value of the counter, not the raw value. Add the following code to retrieve and display the next value of the counter your **PerformanceCounter** instance is watching:

```
' Visual Basic
Private Sub btnGetNextValue_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles btnGetNextValue.Click
   lblSystemCounterValue.Text = _
      "The current value of the system counter is: " _
      & PerformanceCounter1.NextValue().ToString()
End Sub

// C#
private void btnGetNextValue_Click(object sender, System.EventArgs e)
{
   lblSystemCounterValue.Text =
      "The current value of the system counter is: "
      + performanceCounter1.NextValue().ToString();
}
```

For the rest of your procedures, you will work with a custom category and counter.

To create a custom counter and category

1. On the **View** menu, click **Designer** to access the designer for Form1.
2. In the designer, open Server Explorer and access the **Servers** node. For more information, see Accessing and Initializing Server Explorer.
3. Locate the listing for your computer under the **Servers** node and expand it.
4. Right-click the **Performance Counters** node and select **Create New Category** from the shortcut menu.

   The **Performance Counter Builder** dialog box appears.

5. Enter **MyNewCategory** for the **Category name**.
6. Click **New** to add a new counter, and name it **MyNewCounter**. Click **OK** to create the new category and counter.

   > **Note** You will need permission to write to the registry for this step. Contact your system administrator if you are unable to create the new counter.

7. In Server Explorer, browse to the new counter and drag it onto the form. A new **PerformanceCounter** component is added to the project, configured for the new counter, **MyNewCounter**.

   > **Note** These steps create the counter on your computer. If you were to deploy this application, you would need to create the counter on the target computer. You can do this by adding an Installer to the project. Select the **PerformanceCounter** object, and click **Add Installer** in the Properties window. For more information, see Introduction to Installation Components.

To set the raw value of the custom counter

1. In the designer, select the **PerformanceCounter2** in Visual Basic, or **performanceCounter2** in Visual C#.
2. Set the **ReadOnly** property to **false**.
3. Double-click the **btnSetRawValue** button to create the **Click** event handler in the Code Editor.
4. Add the following code to set the raw value of the counter you created and to display the counter's value in the first of the label controls.

```
' Visual Basic
Private Sub btnSetRawValue_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles btnSetRawValue.Click
   PerformanceCounter2.RawValue = CLng(txtValue.Text)
   lblCounterValue.Text = PerformanceCounter2.NextValue().ToString()
End Sub

// C#
private void btnSetRawValue_Click(object sender, System.EventArgs e)
{
   performanceCounter2.RawValue = long.Parse(txtValue.Text);
   lblCounterValue.Text = performanceCounter2.NextValue().ToString();
}
```

To increase the custom counter value by one and display it

1. In the designer, double-click the **Increase the Custom Counter by 1** button to create the **Click** event handler in the Code Editor.
2. Add the following code to add one to your custom counter and to display the counter's value in the first of the label controls.

```
' Visual Basic
Private Sub btnIncrement_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles btnIncrement.Click
   PerformanceCounter2.Increment()
   lblCounterValue.Text = PerformanceCounter2.NextValue().ToString()
End Sub

// C#
private void btnIncrement_Click(object sender, System.EventArgs e)
{
   performanceCounter2.Increment();
   lblCounterValue.Text = performanceCounter2.NextValue().ToString();
}
```

To decrease the custom counter and display its value

1. In the designer, double-click the **Decrease the Custom Counter by 1** button to create the **Click** event handler in the Code Editor.
2. Add the following code to decrease the counter value by one and to display the counter's value in the first of the label controls.

```
' Visual Basic
Private Sub btnDecrement_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles btnDecrement.Click
   PerformanceCounter2.Decrement()
   lblCounterValue.Text = PerformanceCounter2.NextValue().ToString()
End Sub

// C#
private void btnDecrement_Click(object sender, System.EventArgs e)
{
   performanceCounter2.Decrement();
   lblCounterValue.Text = performanceCounter2.NextValue().ToString();
}
```

To increase the custom counter by a user-defined value

1. In the designer, double-click the **Increase Custom Counter by a value** button to create the **Click** event handler in the

Code Editor.

2. Add the following code to increase the counter value by the value entered in the text box and to display the counter's value in the first of the label controls.

```
' Visual Basic
Private Sub btnIncrementBy_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles btnIncrementBy.Click
   PerformanceCounter2.IncrementBy(CLng(txtValue.Text))
   lblCounterValue.Text = PerformanceCounter2.NextValue().ToString()
End Sub

// C#
private void btnIncrementBy_Click(object sender, System.EventArgs e)
{
   performanceCounter2.IncrementBy(long.Parse(txtValue.Text));
   lblCounterValue.Text = performanceCounter2.NextValue().ToString();
}
```

To test your application

1. Save your files.
2. Run the application.
3. Click the **Get Next Value of System Counter** button to retrieve the current value of the Processor category's counter. Since you are retrieving the value using the NextValue() method, the first call will return 0.

   You should see the current value displayed in the label.

4. Type **25** in the text box and click **Set Raw Value of Custom Counter**.

   The label field should be updated to indicate that the raw value is now 25.

5. Click the **Increase Custom Counter by 1** button.

   The value in the label should increase by 1.

6. Click the **Decrease Custom Counter by 1** button.

   The value in the label should decrease by 1.

7. Enter **25** in the text box and click **Increase Custom Counter by a value**.

   The value in the label should increase by 25.

   You can also view your performance counter in the Windows Performance tool.

To view your performance counter in the Windows Performance tool

1. On the taskbar, click the **Start** button, point to **Settings**, and then click **Control Panel**.
2. In **Control Panel**, double-click **Administrative Tools**, and then double-click **Performance**.
3. Right-click the counter list below the performance graph, and select **Add Counters** from the shortcut menu.
4. Select **MyNewCategory** from the **Performance object** list and **MyNewCounter** from the counter list. Click **Add** to finish.
5. Click **View Report** from the toolbar to display the value of your counter.

Logging Application, Server, and Security Events

Windows event logs allow your applications and components to record information about important events. You can use these records to audit access to your system, troubleshoot problems, and re-create usage patterns.

Using the **EventLog** component and language features in Visual Studio .NET or the .NET Framework, you can easily connect to Windows event logs on both local and remote computers and write entries to these logs. You can also read entries from existing logs and create your own custom event logs on computers that have Windows 2000 or Windows NT installed.

Introduction to the EventLog Component

Event logging in Microsoft Windows provides a standard, centralized way for you to have your applications record important software and hardware events. When an error occurs, the system administrator or support technicians must determine what caused the error, attempt to recover any lost data, and prevent the error from recurring. It is helpful if applications, the operating system, and other system services record important events such as low-memory conditions or failed attempts to access a disk. The system administrator can use the event log to help determine what conditions caused the error and the context in which it occurred.

Windows supplies a standard user interface for viewing these event logs and a programming interface for examining log entries. In Microsoft Visual Basic version 6.0, you could perform limited write operations to some event logs, but you could not easily read or interact with all the logs available to you.

Using the **EventLog** component, you can easily connect to event logs on both local and remote computers and write entries to these logs. You can also read entries from existing logs and create your own custom event logs

In addition to writing to event logs and reading their entries, you can use Server Explorer to view a list of the event logs for any server to which you have access. You can expand the **Event Logs** node in Server Explorer to see a list of the logs that currently exist and the events that have been written to them. You can also drag a specific event log from Server Explorer to your designer to create an instance of the **EventLog** component that automatically has its properties set to point to the log you selected.

> **Note** The **Servers** node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.
>
> **Note** You can also use the **GetEventLogs** method to retrieve a list of all event logs on a machine.
>
> **Note** There are security restrictions that affect your ability to use event logs. For more information, see Security Ramifications of Event Logs.

Key Concepts in Windows Event Logs

An *event,* as defined in Windows, is any significant occurrence — whether in the operating system or in an application — that requires users to be notified. Critical events are sent to the user in the form of an immediate message on the screen. Other event notifications are written to one of several *event logs* that record the information for future reference. Every event log entry is classified into one of the following categories: errors, warnings, information, success audits, or failure audits.

There are three event logs available by default on computers running Windows 2000 or Windows NT 4.0:

- a *System log*, which tracks events that occur on system components (for example, a problem with a driver);
- a *Security log*, which tracks security changes and possible breaches;
- an *Application log*, which tracks events that occur in a registered application.

In addition to these logs, other programs such as Active Directory may create their own default logs. You can also create your own custom logs using the language features in the **System.Diagnostics** namespace.

Choosing Events to Log

The following are examples of cases in which event logging can be helpful:

- Resource problems. If an application gets into a low-memory situation (caused by a code bug or inadequate memory) that degrades performance, logging a warning event when memory allocation fails might provide a clue about what went wrong.
- Information events. A server-based application (such as a database server) records a user logging on, opening a database, or starting a file transfer. The server can also log error events it encounters (cannot access file, host process disconnected, and so on), corruptions in the database, or whether a file transfer was successful.

Event logging consumes resources such as disk space and processor time. The amount of disk space that an event log requires and the overhead for an application that logs events depend on how much information you choose to log. Therefore, it is important to log only essential information. It is also best to place event log calls in an error path in the code rather than in the main code path, so as not to reduce performance.

Walkthrough: Exploring Event Logs, Event Sources, and Entries

Types of Event Log Entries

When you write an entry to a log, you specify the type of entry you're making. The following table lists the types of events and their contents.

Entry Type	Contents
Information	An information event indicates an infrequent but significant successful operation. For example, when Microsoft SQL Server successfully loads, it may be appropriate to log an information event stating that "SQL Server has started." Note that while this is appropriate behavior for major server services, it is generally inappropriate for a desktop application to log an event each time it starts.
Warning	A warning event indicates a problem that is not immediately significant but that may cause future complications. Resource consumption is a good candidate for a warning event. For example, an application can log a warning event if disk space is low. If an application can recover from an event without loss of functionality or data, it can generally classify the event as a warning event.
Error	An error event indicates a significant problem the user should know about, such as a loss of functionality or data. For example, if a service cannot be loaded as the system boots, it can log an error event.
Success audit	A success audit event is a security event that occurs when an audited access attempt is successful. For example, a successful logon attempt is a success audit event.
Failure audit	A failure audit event is a security event that occurs when an audited access attempt fails. For example, a failed attempt to open a file is a failure audit event.

By default, the event type is set to **Information** if you do not specify otherwise. You can set the type by using a parameter on an overloaded form of the WriteEntry method. When you are reading log entries, you can query the **EntryType** property on the **EventLogEntry** class to see what type of entry you are working with.

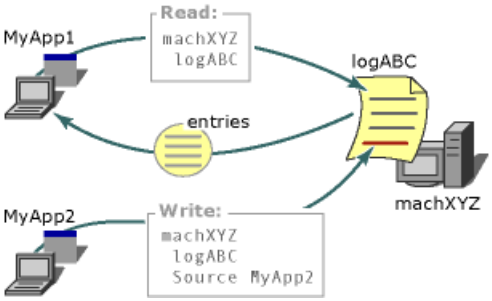
Introduction to the EventLog Component | Event Log References | EventLog Programming Architecture | Walkthrough: Exploring Event Logs, Event Sources, and Entries

Event Log References

There are three default event logs on any computer: an Application event log, a Security event log, and a System event log. In addition to these logs, there may be other logs that are installed by applications on the server and custom logs that are created by users. You identify which of these event logs you want to work with. The method of referencing a specific log differs depending on whether you want to read the log's entries or write entries to the log. The following illustration shows the overall process of referencing logs for read or write operations.

Event Log Referencing



Referencing a Log to Read Entries

When you read entries from an event log, you uniquely identify the log you want by machine name and log name. *Machine name* denotes the server on which the event log exists, and *log name* is simply the name of the log. Machine name is optional; if you do not specify a machine, the local computer is assumed.

For example, suppose you have an instance of the **EventLog** component that you want to use to read entries from a custom log called "OrderEntrySystem, " which is stored on a server named "myserver". You would connect to this log by specifying that:

- The machine name is "myserver"
- The log name is "OrderEntrySystem"

You can retrieve the machine name of a log by querying the **MachineName** property. You can retrieve the log name by querying the **Log** property.

> **Security Note** Treat the data from an event log as you would any other input coming from outside your system. Your application may need to validate the data in the event log before using it as input. Another process, possibly a malicious one, may have accessed the event log and added entries.

Referencing a Log to Write Entries

If you are writing entries to an event log, you must specify the **Source** property. The **Source** property registers your component with the event log as a valid source of entries. You can specify any string as the value for the **Source** property; however, it may be helpful to use the name of your project for this value.

> **Note** If the source is already registered with the log, you do not need to set the log name property to write to the log. You can also not set the machine name; in this case the local machine will be assumed.

For example, suppose you have an instance of the **EventLog** component that you want to use to write entries to a custom log called "OrderEntrySystem", which is stored on the local computer. Assuming that the source has not already been registered, you would connect to this log by specifying that the machine name is ".", the log name is "OrderEntrySystem", and by setting the source to a string of your choice.

> **Note** In this case the period in the machine name indicates the local computer.

A single source can be associated with (and therefore write entries to) only one event log at a time, but a single event log can have many different sources writing to it at once. This means that each instance of the **EventLog** component, when configured to interact with a specific source, can write to only one event log. If you want to write to multiple logs, you must use different instances or change the **Source** property of an existing instance.

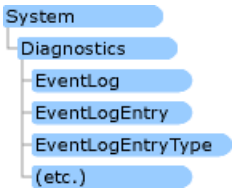
Introduction to the EventLog Component | Walkthrough: Exploring Event Logs, Event Sources, and Entries

EventLog Programming Architecture

The **EventLog** component uses these portions of the .NET Framework namespaces:

EventLog Namespace



When you add an instance of the **EventLog** component to your application in Visual Studio, the system automatically creates the references and import statements you need to access the namespace and classes. However, if you are creating your **EventLog** components in code or in the Microsoft .NET Framework, you might need to create a reference to **System.Diagnostics** and add a statement to your project importing the same library.

For instructions on adding and removing project references, see Adding and Removing References.

Key Programming Elements in the EventLog Class

The **EventLog** component raises an event called EventLog.EntryWritten Event whenever an entry is written to the log you are watching. You can define a handler for this event. In addition, you can use the following methods to interact with an instance of the **EventLog** component:

- You can use the EventLog.Exists (String) method to determine whether a particular event log exists.
- You can use the EventLog.CreateEventSource method to define a string that creates a relationship between a source of events and a log, and use the EventLog.DeleteEventSource method to remove this association. You can also use this method to create new custom event logs. Just type a new log name as the log in which you want to create your source, and the system will create the log automatically.

  > **Note** You can set the EventLog.Source property to any string; it does not have to correspond to the name of your application. A single application can contain multiple components that use different source strings to identify themselves to event logs.

- You can use the EventLog.WriteEntry method to write event information to any event log to which you have access. The **WriteEntry** method automatically registers your component or application as a valid source if it is not already registered with the designated log.
- You can use the EventLog.SourceExists method to determine whether a particular source is already registered. This is useful when you are attempting to create a new source on a given computer, because the **CreateEventSource** method will cause a run-time error if the source is already registered on that computer.
- You can use the EventLog.GetEventLogs method to retrieve a list of all the event logs on a particular computer.
- You can use the EventLog.Delete method to delete an entire event log. Use this method with caution, as deleting a log will also delete any sources registered in it.

Related Sections

Introduction to the EventLog Component
Provides an overview of the **EventLog** component and how you can use it to interact with existing logs.

Deleting Event Logs

You can delete any event log on your local computer or a remote server, provided you have the appropriate registry rights. When you delete a log, the system first deletes the file that contains the log's contents and then accesses the registry and removes the registration for all of the event sources that were registered for that log. Even if you re-create the log at a later point, this process will not create the sources by default, so some applications that previously were able to write entries to that log may not be able to write to the new log.

You must have registry rights on the machine on which you want to delete a log. For more information, see your Windows documentation.

> **Note** Re-creating an event log can be a difficult process. It is good practice to not delete any of the system-created event logs, such as the Application log. You can delete your custom logs and re-create them as needed.

To delete an event log

- Call the **Delete** method and specify the name of the log you want to delete.

```
' Visual Basic
EventLog.Delete("MyCustomLog")

// C#
System.Diagnostics.EventLog.Delete ("MyCustomLog");
```

> **Note** Because the **Delete** method is static, you do not need to create an instance of the **EventLog** component before you call the method — instead, you can call the method on the **EventLog** class itself.
>
> **Tip** To delete an event log on a remote computer, specify the name of the computer as a second parameter.

The following code shows an example of verifying a source and deleting a log if the source exists. This code assumes that an **Imports** or **Using** statement exists for the **System.Diagnostics** namespace:

```
' Visual Basic
If EventLog.Exists("MyCustomLog") Then
   EventLog.Delete("MyCustomLog")
End If

// C#
if (System.Diagnostics.EventLog.Exists("MyCustomLog"))
{
   System.Diagnostics.EventLog.Delete("MyCustomLog");
}
```

See Also

Administering Event Logs | Security Ramifications of Event Logs | Walkthrough: Exploring Event Logs, Event Sources, and Entries

Determining If Specific Event Logs Exist

You can use the EventLog.Exists method to determine whether a specific log exists. If the log exists, the method returns **true**. You might use this method if you are creating a custom log and want to make sure that a log by that name does not already exist.

You must have registry rights in order to find out if a log exists. If you do not have the appropriate rights, the query will always return **false**. For information on setting registry rights, see your Windows documentation.

In addition to the **Exists** method, you can use a similar method, the EventLog.SourceExists method, to determine if a particular source string exists. See Determining If an Event Source Exists for more information.

> **Note** Because the **Exists** and **SourceExists** methods are static, you do not need to create an instance of the **EventLog** component before you call either method — instead, you can call the method on the **EventLog** class itself.

You must have appropriate access rights on the remote machines to create and delete logs. For more information, see Security Ramifications of Event Logs.

To determine if an event log exists

- Call the **Exists** method, specifying the log on the local computer that you want to verify as a parameter.

  The following example shows how to determine whether the Application log exists on the local machine. This code assumes that an **Imports** or **Using** statement exists for the **System.Diagnostics** namespace:

  ```
  ' Visual Basic
  Dim logExists As Boolean
  logExists = EventLog.Exists("Application")

  // C#
  bool logExists = System.Diagnostics.EventLog.Exists("Application");
  ```

  If the log exists, the message box will show "True." If it does not exist, the message box will show "False."

  > **Tip** You can specify a computer name as a second parameter to determine if an event log exists on a remote computer.

  > **Note** **Application** is case sensitive.

See Also

Administering Event Logs | Creating and Removing Custom Event Logs | Security Ramifications of Event Logs | Walkthrough: Exploring Event Logs, Event Sources, and Entries

Creating and Removing Custom Event Logs

You can use the **EventLog** class to create a custom event log on a local or remote computer. You might create a custom log if you wanted to organize your entries in a more granular way than is allowed when your components write entries to the default Application log. For example, suppose you have a component called OrderEntry that writes entry information to an event log. You are interested in backing up and saving these entries for a longer period of time than some other entries in the Application log. Rather than registering your component to write to the Application log, you can create a custom log called OrdersLog and register your component to write entries to that log instead. That way, all of your order information is stored in one place and will not be affected if the entries in the Application log are cleared.

You can indirectly use the **CreateEventSource** method to create a custom log. This method creates a new source and lets you specify the log to write to. If you specify that you want to write to a log that does not already exist, the system automatically creates a custom log for you and registers your component as a source for that log.

> **Note** You remove a custom log the same way you remove any log — by calling the **Delete** method. For more information, see Deleting Event Logs.

It is important to note the difference between creating an event log and creating an instance of the **EventLog** component. When you use the **CreateEventSource** method, you are creating a new custom event log in Windows, rather than a component in your project or application. When you create an instance of the **EventLog** component, you create a component inside your project that references an external event log. You can view the event logs created with the **CreateEventSource** method in the Event Viewer, but you cannot view component instances there.

You can view custom logs in Server Explorer, or in the Windows 2000 Computer Management window. For more information, see Working with Event Logs in Server Explorer or Launching Event Viewer.

> **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

You must have appropriate access rights on the remote machines to create and delete logs. For more information, see Security Ramifications of Event Logs.

> **Security Note** When you create an event log, be aware that the resource may already exist. Another process, perhaps a malicious one, may have already created the resource and have access to it. When you put data in the event log, the data is available to the other process. For information on existing event logs, see Determining If Specific Event Logs Exist.

To create a custom event log

- Call the **CreateEventSource** method and specify the source string and the name of the log file you want to create.

  > **Note** If you specify null ("") as the log name, it defaults to **Application**. This will not create a new log, but will register the specified source for the Application log. If you create a new log, only the first eight letters are evaluated when determining if the name is unique.

  The following example shows how to create a custom log called MyNewLog on the local machine. This code assumes that an **Imports** or **Using** statement exists for the **System.Diagnostics** namespace:

  ```
  ' Visual Basic
  EventLog.CreateEventSource("MyApp1", "MyNewLog")

  // C#
  System.Diagnostics.EventLog.CreateEventSource("MyApp1", "MyNewLog");
  ```

  To create a custom event log on a remote machine, specify the machine name as a third parameter. The following code shows an example.

  ```
  ' Visual Basic
  EventLog.CreateEventSource("MyApp1", "MyNewLog", "myserver")

  // C#
  System.Diagnostics.EventLog.CreateEventSource(
```

```
    "MyApp1", "MyNewLog", "myserver");
```

Administering Event Logs | Deleting Event Logs | Working with Event Logs in Server Explorer | Launching Event Viewer | Security Ramifications of Event Logs

Clearing Event Logs

Event logs are set to a maximum size that determines how many entries each log can contain. When an event log is full, it will either stop recording entries or begin overwriting the oldest entries with new entries, depending on the log's settings in the Windows Event Viewer. In either case, you can clear the log of its existing entries to free the log and allow it to start recording events again. You must have Administrator rights to the computer on which the log resides in order to clear entries.

By default, the Application, System, and Security logs are set to a default maximum size of 4992 K. Custom logs are set to a default maximum of 512 K.

> **Note** You can also use the Windows Event Viewer to free up space on a log that has become full. You can set the log to overwrite existing events, you can write log entries to an external file, or you can increase the maximum size of the log. You cannot, however, remove only some of the entries in a log; when you clear a log, you remove all of its contents. For more information, see Launching Event Viewer or your Event Viewer documentation.

To clear an event log's contents from Server Explorer

1. Open **Server Explorer**, and then expand the node for the server on which the event log you want to clear resides. For more information, see Accessing and Initializing Server Explorer.

   > **Tip** If you do not see the server you want listed in the **Servers** node, right-click **Servers**, click **Add Server**, enter the name of your server, and then click **OK**.

   > **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

2. Expand the **Event Logs** node.

   You will see a list of the three main event logs — Application, Security, and System.

3. Right-click the log node you want to clear, and then click **Clear Event Log**.
4. Click **Yes** when prompted to confirm the deletion.

To clear an event log's contents programmatically

1. Create an instance of the **EventLog** component and set the necessary properties to configure it. For more information, see Creating EventLog Component Instances and Configuring EventLog Component Instances.
2. Use the EventLog.Clear method to clear the contents of the appropriate event log.

   Your code should look something like this:

```
' Visual Basic
EventLog1.Clear()

// C#
EventLog1.Clear();
```

Working with Event Logs in Server Explorer | Launching Event Viewer | Accessing and Initializing Server Explorer | Administering Event Logs | Walkthrough: Exploring Event Logs, Event Sources, and Entries

Creating EventLog Component Instances

You create **EventLog** components when you want to add event log functionality to your application. **EventLog** components allow you to connect to existing event logs, write entries to them, and react to entries the logs receive.

EventLog components have no visual user interface. If you add an instance of the **EventLog** component to a visual item (such as a form), the component appears in a small area below the bottom border of the form. This is known as the component tray and acts as a place to display all of the non-visual items associated with the form.

> **Note** Non-visual classes that inherit from **System.ComponentModel.Component** support a visual design surface similar to the component tray, on which your **EventLog** component and other components are arranged. The arrangement of items on this designer is not important, as the interface you see will never be displayed to the application's end users.

There are several ways you can create an instance of the **EventLog** component:

- You can drag an instance of the **EventLog** component from the **Components** tab of the **Toolbox** to a form or other designer.
- You can locate the log you want in Server Explorer and add it to your designer, creating an instance of the **EventLog** component that is pre-configured to point to that log.
- You can create an instance of the **EventLog** component in code.

To create an EventLog component instance from Server Explorer

1. Open **Server Explorer**. For more information, see Accessing and Initializing Server Explorer.
2. Expand the node for the server you want to view, and then locate and expand the **Event Logs** node beneath it.

   > **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

3. Locate the log you want to add to your project, and then right-click it.
4. Click **Add to Designer**.
5. Set the necessary properties for the component. For more information, see Configuring EventLog Component Instances.

To create an EventLog component instance from the Toolbox

1. Access the **Components** tab of the **Toolbox**.
2. Select the **EventLog** icon and drag it to the designer surface for your form or component.
3. Set the necessary properties for the component. For more information, see Configuring EventLog Component Instances.

To create an EventLog component instance programmatically

1. Create an instance of the **EventLog** class in code. Your code might look like this:

```
' Visual Basic
Dim EventLog1 As New System.Diagnostics.EventLog()

// C#
System.Diagnostics.EventLog EventLog1 = new System.Diagnostics.EventLog();
```

2. Set the necessary properties for the component. For more information, see Configuring EventLog Component Instances.

Introduction to the EventLog Component | Configuring EventLog Component Instances | Adding Your Application as a Source of Event Log Entries | Determining If an Event Source Exists | Removing an Event Source | Walkthrough: Exploring Event Logs, Event Sources, and Entries

Configuring EventLog Component Instances

There are three major properties involved in configuring an instance of the **EventLog** component:

- The Log property indicates the log with which you want to interact.
- The MachineName property indicates the computer on which the log you are working with resides.
- The Source property indicates the source string which will be used to identify your component when it writes entries to a log.

The way you configure your **EventLog** component instance depends on how you are planning to use it:

- If you are planning to write entries to a log, you must do one of two things. Either you must register a source using the EventLog.CreateEventSource method and set the **EventLog** component's **Source** property to that same source, or you must set the **MachineName**, **Log**, and **Source** properties for the component.

  > **Note** You can set the **Log** property on your component directly, or you can set it in code that registers your component as an event source. After registering the component as a source, a connection is already set in the server's registry linking your component to a specific log.

- If you are planning to read log entries or monitor a log, you must set the **MachineName** and **Log** properties to indicate the log you are watching. You do not need to set the **Source** property in this case.
- If you want your component to be able to receive notification of **EntryWritten** events, you must set EventLog.EnableRaisingEvents to **true**. For more information, see Handling the EntryWritten Event.

  The following example shows how to configure your component to allow you to write entries to the Application log. In this case, the source has not already been registered with the log, so you must specify the source string, log, and machine name. You do not need to explicitly call the **CreateEventSource** method because the EventLog.WriteEntry call will register the source with the log if it has not already been registered.

```
' Visual Basic
Dim EventLog1 As New EventLog("Application", "myserver", "newsource")
EventLog1.WriteEntry("Test")

// C#
System.Diagnostics.EventLog EventLog1 = new
   System.Diagnostics.EventLog("Application", "myserver", "newsource");
EventLog1.WriteEntry("Test");
```

  If the source has already been registered, you can simply set the **Source** property and write your entry. For example, the following code shows how to write an entry to a log using a source that has already been registered.

```
' Visual Basic
If Not EventLog.SourceExists("ExistingSourceString") Then
    EventLog.CreateEventSource("ExistingSourceString", "Application")
End If
Dim EventLog1 As New EventLog()
EventLog1.Source = "ExistingSourceString"
EventLog1.WriteEntry("TestEntry2")

// C#
if (!System.Diagnostics.EventLog.SourceExists("ExistingSourceString"))
   System.Diagnostics.EventLog.CreateEventSource(
      "ExistingSourceString", "Application");

System.Diagnostics.EventLog EventLog1 =
   new System.Diagnostics.EventLog();
EventLog1.Source = "ExistingSourceString";
EventLog1.WriteEntry("TestEntry2");
```

Note If you do not set the **MachineName** property, as shown in these examples, the local machine is assumed.

For more information on these properties, see Event Log References.

The entries you retrieve from an event log are categorized by multiple properties. For information on these properties, see EventLogEntry Members.

To configure an instance of the EventLog component

1. Create an instance of the **EventLog** component. For more information, see Creating EventLog Component Instances.
2. Set the appropriate combination of the **Log**, **MachineName**, and **Source** properties:

If you will be	**Do this**
Reading or monitoring event logs	Set **Log** and **MachineName**
Writing entries to a log using a new **Source** string	Set **Source**, **Log**, and **MachineName**
Writing entries to a log for an existing **Source**	Set the **Source** property to the existing source; the other properties will be set automatically

3. To enable your component instance to receive notifications of the **EntryWritten** event, set the **EnableRaisingEvents** property to **true**.

Event Log References | Creating EventLog Component Instances | Adding Your Application as a Source of Event Log Entries | Writing Entries to Event Logs

Adding Your Application as a Source of Event Log Entries

Before your component can write an entry to an event log, you must register it with the event log as a valid source of events. You can do this by using the EventLog.CreateEventSource method and specifying a string that uniquely identifies your component to the event log. When you write a log entry, the system uses the source you identified to find the appropriate log in which to place your entry. Your **EventLog** component instance can write to only a single log at a time.

> **Note** By default, if you try to write an entry without first having registered your component as a valid source, the system automatically registers the source with the event log, using the value of the **Source** property as the source string.

If you specify the name of a log that does not exist when you use the **CreateEventSource** method, the system creates a new, custom event log for you with that name the first time you try to write an entry to the log. For more information, see Creating and Removing Custom Event Logs.

To establish your component as an event source

- To create entries on the local machine, call the **CreateEventSource** method and specify the source string and log name as parameters.

  > **Note** If you specify null (" ") for the log name, it defaults to **Application**.

  The following example shows how to register your component MyApp1 as a source for the Application log. This code assumes that an **Imports** or **Using** statement exists for the **System.Diagnostics** namespace:

```
' Visual Basic
EventLog.CreateEventSource("MyApp1", "Application")

// C#
System.Diagnostics.EventLog.CreateEventSource("MyApp1", "Application");
```

  > **Tip** To create an event source on a remote computer, specify the machine name as a third parameter. The following code shows an example:

```
' Visual Basic
EventLog.CreateEventSource("MyApp1", "Application", "myserver")

// C#
System.Diagnostics.EventLog.CreateEventSource(
   "MyApp1", "Application", "myserver");
```

See Also

Determining If an Event Source Exists | Removing an Event Source | Introduction to the EventLog Component | Creating and Removing Custom Event Logs | Walkthrough: Exploring Event Logs, Event Sources, and Entries

Determining If an Event Source Exists

Once you identify a source for a particular event log, this information is stored in the server's registry files until you remove that source. If you try to re-register a source that has already been registered as a valid source for a given log, the system raises a run-time error. You can use the EventLog.SourceExists method to determine whether or not a particular source has already been registered.

To determine if a source has already been registered

- Call the **SourceExists** method, specifying the source name to query.

  The following example shows how to determine if a source using the string MyApp1 is already registered, and to register it with the Application log if it is not.

```
' Visual Basic
If Not EventLog.SourceExists("MyApp1") Then
    EventLog.CreateEventSource("MyApp1", "Application")
End If

// C#
if (!System.Diagnostics.EventLog.SourceExists("MyApp1"))
   System.Diagnostics.EventLog.CreateEventSource(
      "MyApp1", "Application");
```

  To determine if a source is registered on a remote computer, specify the computer name as a second parameter. The following code shows an example:

```
' Visual Basic
If Not EventLog.SourceExists("MyApp1", "myserver") Then
    EventLog.CreateEventSource("MyApp1", "Application", "myserver")
End If

// C#
if (!System.Diagnostics.EventLog.SourceExists("MyApp1", "myserver"))
   System.Diagnostics.EventLog.CreateEventSource(
      "MyApp1", "Application", "myserver");
```

See Also

Removing an Event Source | Adding Your Application as a Source of Event Log Entries | Walkthrough: Exploring Event Logs, Event Sources, and Entries

Removing an Event Source

You can remove your source if you no longer need to use it to write entries to that log. Doing so affects all components that used that source to write to the log. For example, if you have two components that write to a log using the source string "mysource," removing "mysource" as a valid source of events affects both the components.

You might remove an event source if you were changing your source from one log to another. For example, suppose you want to stop writing entries to an OrdersProcessed log and start writing entries to an OrdersSent log. First, you would remove the association of the source with the first log, and then you would register the source with the new log to which you wanted to write events.

To remove an event source

- Call the EventLog.DeleteEventSource method, specifying the source name to remove.

  The following example shows how to unregister an event source named MyApp1 from the local machine. This code assumes that an **Imports** or **Using** statement exists for the **System.Diagnostics** namespace:

```
' Visual Basic
EventLog.DeleteEventSource("MyApp1")

// C#
System.Diagnostics.EventLog.DeleteEventSource("MyApp1");
```

  Tip To remove an event source from a remote computer, specify the computer name as a second parameter. The following code shows an example:

```
' Visual Basic
EventLog.DeleteEventSource("MyApp1", "myserver")

// C#
System.Diagnostics.EventLog.DeleteEventSource("MyApp1", "myserver");
```

  Note Removing a source does not remove the entries that were written to that log using this source. However, it does affect the entries by adding information to them indicating that the source cannot be found.

Determining If an Event Source Exists | Adding Your Application as a Source of Event Log Entries | Walkthrough: Exploring Event Logs, Event Sources, and Entries

Writing Entries to Event Logs

When you write an entry to an event log, you specify the message you want to write to the log as a string. A message should contain all information needed to interpret what caused the problem and what to do to correct the problem.

There are two ways you can write an entry to the log; both are equally valid. The most direct way is to register an event source with the log to which you want to write, then instantiate a component and set its **Source** property to that log, and finally call **WriteEntry**. If you do this, you do not have to set the **Log** property for the component instance; the log is automatically determined when you connect to a source that has already been registered. For more information on registering a source, see Adding Your Application as a Source of Event Log Entries.

The other way to approach this process is to instantiate an **EventLog** component, set its **Source**, **Machine**, and **Log** properties, and call the **WriteEntry** method. In this case, the **WriteEntry** method would determine whether the source already existed and register it on the fly if it did not.

The following conditions must be met in order to successfully write a log entry:

- The source must be registered with the desired log.

  > **Note** You must set the **Source** property on your **EventLog** component instance before you can write entries to a log. When your component writes an entry, the system automatically checks to see if the source you specified is registered with the event log to which the component is writing, and calls **CreateEventSource** if needed.

- The message you specify cannot be more than 16K in length.
- Your application must have write access to the log to which it is attempting to write. For more information, see Security Ramifications of Event Logs.

You can specify several parameters when you write an entry, including the type of entry you're making, an ID that identifies the event, a category, and any binary data you want to append to the entry. For more information on the properties associated with an entry, see EventLog Members.

To write an event log entry

1. Instantiate an **EventLog** component. For more information, see Creating EventLog Component Instances.
2. Use the EventLog.CreateEventSource method to register an event source with the log to which you want to write an entry, using a unique string for the source string. Set the **Source** property for the component to the source you registered. For more information, see Configuring EventLog Component Instances. Call the **WriteEntry** method to specify the entry to be written to the log.

```
' Visual Basic
If Not EventLog.SourceExists("MyApp1") Then
    EventLog.CreateEventSource("MyApp1", "Application")
End If
EventLog1.Source = "MyApp1"
EventLog1.WriteEntry("This is a simple event log entry")

// C#
if (!System.Diagnostics.EventLog.SourceExists("MyApp1"))
   System.Diagnostics.EventLog.CreateEventSource(
      "MyApp1", "Application");

EventLog1.Source = "MyApp";
EventLog1.WriteEntry ("This is a simple event log entry");
```

Introduction to the EventLog Component | Configuring EventLog Component Instances | Creating EventLog Component Instances | EventLog Members | Adding Your Application as a Source of Event Log Entries | Walkthrough: Exploring Event Logs, Event Sources, and Entries

Reading Event Log Entries

You use the **Entries** collection to look at the entries in a particular event log. You can use standard collection properties such as **Count** and **Item** to work with the elements the collection contains. You might read event log entries to find out more information about a problem that occurred in your system, to identify usage patterns, or to identify problems (such as a failing hard drive) before they cause damage.

> **Note** The **Entries** collection is read-only; to write a message to a log you must use the **WriteEntry** method. For information, see Writing Entries to Event Logs.

If you ask for the count of entries in a new custom log that has not yet been written to, the system will return the count of the entries in the Application log on that server. Make sure that logs you are counting have been created and written to in order to avoid this problem.

> **Note** There are security restrictions that affect your ability to use event logs. For more information, see Security Ramifications of Event Logs.
>
> **Security Note** Treat the data from an event log as you would any other input coming from outside your system. Your application may need to validate the data in the event log before using it as input. Another process, possibly a malicious one, may have accessed the event log and added entries.

To read event log entries

1. Create an instance of the **EventLog** component. For more information, see Creating EventLog Component Instances.
2. Set the **Log** and **MachineName** properties for the component. For more information, see Configuring EventLog Component Instances.
3. Use the **Entries** collection to review the entries in the log. The following example shows how to retrieve all of the entries from a log.

```
' Visual Basic
Dim entry As EventLogEntry
For Each entry In EventLog1.Entries
   Console.WriteLine(entry.Message)
Next

// C#
foreach (System.Diagnostics.EventLogEntry entry in EventLog1.Entries)
{
   Console.WriteLine(entry.Message);
}
```

See Also

Introduction to the EventLog Component | Handling the EntryWritten Event | Walkthrough: Exploring Event Logs, Event Sources, and Entries

Handling the EntryWritten Event

You can create event handlers for your **EventLog** components that automatically call a procedure when an entry is written to a log. There are several ways you can create an event handler for an instance of the **EventLog** component, but the simplest way is to let Visual Studio .NET handle most of the syntax for you automatically. When you double-click your **EventLog** component in the designer, Visual Studio moves you to the Code Editor and creates the event handler and the blank procedure it calls. You can then fill in the processing that you want to occur in the **EntryWritten** procedure.

For more information on event handlers, see Event Handlers in Visual Basic and Visual C#.

To create a default handler for the EntryWritten event

1. From the designer, double click on the **EventLog** component for which you want to create a handler.

   Note The Code Editor appears and two items are added to your code: the handler that creates and registers a delegate and calls the procedure, and a blank procedure for the EventLog.EntryWritten Event event.

2. In the blank procedure for the **EntryWritten** event, define code to receive and process entries when this event is called. Your code might look like this:

```
' Visual Basic
Private Sub EventLog1_EntryWritten(ByVal sender As System.Object, _
   ByVal e As System.Diagnostics.EntryWrittenEventArgs) _
   Handles EventLog1.EntryWritten

   If e.Entry.Source = "MyApplication" Then
      Console.WriteLine("Entry written by my app. Message: " & _
         e.Entry.Message)
   Else
      Console.WriteLine("Entry written by another application. ")
   End If
End Sub

// C#
private void eventLog1_EntryWritten(object sender,
   System.Diagnostics.EntryWrittenEventArgs e)
{
   if (e.Entry.Source == "MyApplication")
      Console.WriteLine("Entry written by my application. Message: "
         + e.Entry.Message);
   else
      Console.WriteLine("Entry was written by another application.");
}
```

3. Set the **EnableRaisingEvents** property to **true**.

To create a handler programmatically

1. Use the **AddHandler** method to create an event handler of type **EventLogEventHandler** for your component that will call the **EventLog1.EntryWritten** procedure when an entry is written to the log. Your code should look like this:

```
' Visual Basic
AddHandler EventLog1.EntryWritten, _
   New System.Diagnostics.EntryWrittenEventHandler( _
   AddressOf Me.EventLog1_EntryWritten)

// C#
this.eventLog1.EntryWritten += new
   System.Diagnostics.EntryWrittenEventHandler(
   this.eventLog1_EntryWritten);
```

Note For more information on this syntax, see Event Handlers in Visual Basic and Visual C#.

2. Create the **EntryWritten** procedure and define the code you want to process the entries.
3. Set the **EnableRaisingEvents** property to **true**.

See Also

Event Handlers in Visual Basic and Visual C#| Configuring EventLog Component Instances |
Configuring EventLog Component Instances

Working with Event Logs in Server Explorer

Using Server Explorer, you can explore existing event logs on any computer to which you have access. You can view any log available on these computers, including those logs you create from Visual Studio. NET.

> **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features. You can also see information about event logs in the Microsoft Windows 2000 Computer Management window. For more information, see Launching Event Viewer.

To locate an event log in Server Explorer

1. Expand the **Servers** node, and then expand the node for the server you want to view.

   > **Tip** If the server you want to view is not listed, you need to add it. For more information, see Accessing and Initializing Server Explorer.

2. Locate and expand the **Event Logs** node beneath it.

To locate a log in Computer Management on a Windows 2000 server

1. On the desktop for your computer, right-click **My Computer**, and then click **Manage**.
2. In the dialog box that appears, expand the **System Tools** node.
3. Expand the **Event Viewer** node. A full list of the event logs on the computer appears. You can click any log to see the entries it contains.

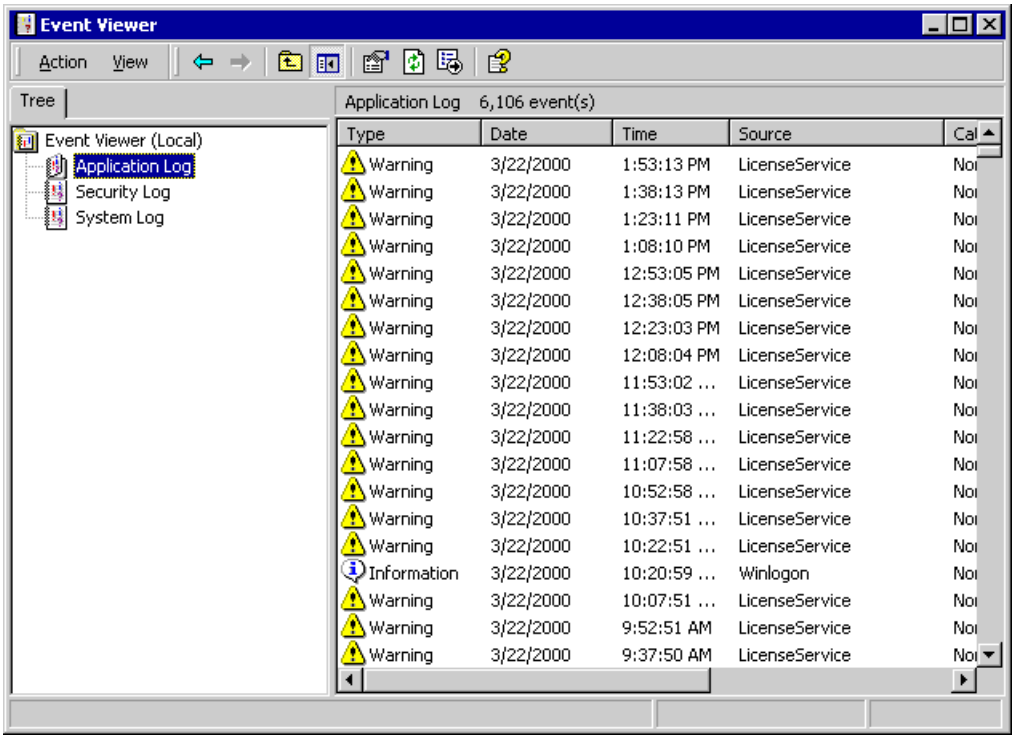
See Also

Introduction to the EventLog Component | Launching Event Viewer | Clearing Event Logs | Accessing and Initializing Server Explorer

Launching Event Viewer

Event Viewer is a Microsoft Windows 2000 application that allows you to monitor and administer event logs and their entries. You can launch the Event Viewer application from Server Explorer if you want to access the information it contains directly rather than through your Visual Studio .NET code. The following illustration shows the Event Viewer window.

Event Viewer Window



To launch Event Viewer

1. Access **Server Explorer** and locate the **Event Logs** node. For more information, see Accessing and Initializing Server Explorer.
2. Expand the **Servers** node.
3. Right-click the **Event Logs** node and select **Launch Event Viewer**.

See Also

Working with Event Logs in Server Explorer | Clearing Event Logs | Accessing and Initializing Server Explorer

Security Ramifications of Event Logs

Access to the event logs is determined by the account under which the application is running. The LocalSystem account is a special account that service applications can use. The Administrator account consists of the administrators for the system. The Server Operator account (ServerOp) consists of the administrators of the domain server. The World account includes all users on all systems.

The following table shows the accounts that are granted Read, Write, and Clear access to each log.

Log	Account	Access
Application	LocalSystem	Read Write Clear
	Administrator	Read Write Clear
	ServerOp	Read Write Clear
	World	Read Write
Security	LocalSystem	Read Write Clear
	Administrator	Read Write
	World	None
System	LocalSystem	Read Write Clear
	Administrator	Read Write Clear
	World	Read Clear
	ServerOp	Read

In addition, users can read and clear the Security log if they have been granted one of the following:

- The "manage auditing and Security log" user right.
- The SE_AUDIT_NAME privilege. For more information, see Authorization Data Types and Constants.

For more information, see your Windows documentation.

If you are using event logs in an ASP.NET application, access to the event logs is through another account, the ASPNET account. The default settings of the ASPNET user account restrict access to the event logs. The ASPNET user account does not have permission to create new categories, though it can add entries to an existing log. You can use impersonation with the ASPNET account to allow creation of new categories. The impersonation identity must have sufficient privileges to create categories. If your application needs event logs that can be specified before deployment, they can be created by the deployment project. For more information, see ASP.NET Web Application Security.

When you create an event log, be aware that the resource may already exist. Another process, perhaps a malicious one, may have already created the resource and have access to it. When you put data in the event log, the data is available to the other process. For information on existing event logs, see Determining If Specific Event Logs Exist.

Introduction to the EventLog Component

Walkthrough: Exploring Event Logs, Event Sources, and Entries

This walkthrough will take you through the major feature areas of event logging in your Visual Studio application. During this walkthrough, you will learn how to:

- Create an **EventLog** component.
- Write code to create and delete custom event logs.
- Write entries of various types to the custom log.
- Read entries from the custom log.
- Verify the existence of logs and event sources.
- Clear log entries.
- Use Server Explorer to verify the results of your event log actions.

Creating the User Interface

In this walkthrough, you will create a Windows Form and use a series of controls on it to launch a series of event-logging actions.

To create the form and controls for your application

1. From the **New Project** dialog box, create a Visual Basic or C# Windows Application, and name it **EventLogApp1**.
2. Add eight buttons to the Windows Form, and set the following properties for them:

Control	Text Property	Name Property
Button1	**Create Custom Log**	**CreateLog**
Button2	**Delete Log**	**DeleteLog**
Button3	**Write Entry**	**WriteEntry**
Button4	**Clear Log**	**ClearLog**
Button5	**Verify Log Exists**	**VerifyLog**
Button6	**Verify Source Exists**	**VerifySource**
Button7	**Remove Event Source**	**RemoveSource**
Button8	**Read Entry**	**ReadEntry**

3. In turn, do the following for each button:
   a. In the designer, double-click the button to create a default event handler for that button. The Code Editor appears and a sub for the button's **Click** event appears.
   b. Return to Design view, and double-click the next button.
   c. Continue until you have created a default event handler sub for each button.
4. From the **Components** tab of the Toolbox, drag an **EventLog** component to the form.

   An **EventLog** component instance appears in the component tray area at the bottom of the form.

Creating and Deleting a Custom Log

In this procedure, you will use the **SourceExists** method to verify that the source you are using does not already exist, and then you will call the **CreateEventSource** method with the name of a log that does not exist. Because this log does not exist, the system will create a custom log for you when this code is run.

To create the custom log

1. In the Code Editor, locate the **CreateLog_Click** procedure.
2. Type in the following code. The event log and source are created as a pair, and the source cannot already exist before the event log is created. After creating the event log, the **EventLog** component is configured to access the new event log.

```
' Visual Basic
' Source cannot already exist before creating the log.
If EventLog.SourceExists("Source1") Then
   EventLog.DeleteEventSource("Source1")
End If

' Logs and Sources are created as a pair.
EventLog.CreateEventSource("Source1", "NewLog1")
```

```
' Associate the EventLog component with the new log.
EventLog1.Log = "NewLog1"
EventLog1.Source = "Source1"

// C#
// Source cannot already exist before creating the log.
if (System.Diagnostics.EventLog.SourceExists("Source1"))
{
   System.Diagnostics.EventLog.DeleteEventSource("Source1");
}

// Logs and Sources are created as a pair.
System.Diagnostics.EventLog.CreateEventSource("Source1", "NewLog1");
// Associate the EventLog component with the new log.
eventLog1.Log = "NewLog1";
eventLog1.Source = "Source1";
```

Security Note When you create an event log, you need to decide what to do if that resource already exists. Another process, perhaps a malicious one, may have already created the event log and have access to it. When you put data in the event log, the data is available to the other process.

To delete a custom log

1. In the Code Editor, locate the **DeleteLog_Click** procedure.
2. Type in the following code:

```
' Visual Basic
If EventLog.Exists("NewLog1") Then
   EventLog.Delete("NewLog1")
End If

// C#
if (System.Diagnostics.EventLog.Exists("NewLog1"))
{
   System.Diagnostics.EventLog.Delete("NewLog1");
}
```

Writing Entries to the Log

In this procedure, you will use the **EventLog** component instance you created to write entries to the log. To do so, you will first configure the component to use the source string you just created, then you will specify two entries to write: an informational event and an error event.

To write entries to the log

1. In the Code Editor, locate the **WriteEntry_Click** procedure.
2. Type in the following code. This code uses the overloaded EventLog.WriteEntry method to write to the event log. The second form shown allows you to specify the type of message. If you view the entries using the Server Explorer in the "Testing Your Code" section below, the different types of entries are indicated by different icons.

```
' Visual Basic
EventLog1.WriteEntry("This is an informational message")
EventLog1.WriteEntry("This is an error message", _
   Diagnostics.EventLogEntryType.Error)

// C#
eventLog1.WriteEntry("This is an informational message");
eventLog1.WriteEntry("This is an error message",
   System.Diagnostics.EventLogEntryType.Error);
```

Clearing Log Entries

In this procedure, you will use the **Clear** method to remove existing entries from the custom log.

To clear log entries

1. In the Code Editor, locate the **ClearLog_Click** procedure.
2. Call the **Clear** method on the **EventLog** component instance:

```
' Visual Basic
EventLog1.Clear()

// C#
eventLog1.Clear();
```

Verifying Logs and Sources

In this procedure, you will create two procedures: one that verifies the existence of the custom log, and one that verifies the existence of your source string. These procedures will be used to test the results of various actions you perform when you run the project.

To verify that the custom log exists

1. In the Code Editor, locate the **VerifyLog_Click** procedure.
2. Create a message box that evaluates whether the specified event log exists and displays true or false accordingly. Use this code:

```
' Visual Basic
Dim logExists As Boolean = EventLog.Exists("NewLog1")
MessageBox.Show("Does the log exist? " & logExists.ToString())

// C#
bool logExists = System.Diagnostics.EventLog.Exists("NewLog1");
MessageBox.Show("Does the log exist? " + logExists.ToString());
```

To verify that the source exists

1. In the Code Editor, locate the **VerifySource_Click** procedure.
2. Create a message box that evaluates whether the specified source exists and displays true or false accordingly. Use this code:

```
' Visual Basic
Dim sourceExists As Boolean = EventLog.SourceExists("Source1")
MessageBox.Show("Does the source exist? " + sourceExists.ToString())

// C#
bool sourceExists =
   System.Diagnostics.EventLog.SourceExists("Source1");
MessageBox.Show("Does the source exist? " + sourceExists.ToString());
```

Removing Sources

In this procedure, you will write code to delete a source string. To do so, you will first verify that the source in question (Source1) exists, then call the **DeleteEventSource** method to remove it.

To remove the event source you created

1. In the Code Editor, locate the **RemoveSource_Click** procedure.
2. Add the following code:

```
' Visual Basic
If EventLog.SourceExists("Source1") Then
```

```
   EventLog.DeleteEventSource("Source1")
End If

// C#
if (System.Diagnostics.EventLog.SourceExists("Source1"))
{
   System.Diagnostics.EventLog.DeleteEventSource("Source1");
}
```

Reading Entries

In this procedure, you will write code to iterate through the event log's entries collection and display the existing messages in the log.

To read entries from the custom log you created

1. In the Code Editor, locate the **ReadEntry_Click** procedure.
2. Add the following code:

```
' Visual Basic
Dim entry As EventLogEntry
If EventLog1.Entries.Count > 0 Then
   For Each entry In EventLog1.Entries
      System.Windows.Forms.MessageBox.Show(entry.Message)
   Next
Else
   MessageBox.Show("There are no entries in the log.")
End If

// C#
if (eventLog1.Entries.Count > 0)
{
   foreach (System.Diagnostics.EventLogEntry entry
      in eventLog1.Entries)
   {
      MessageBox.Show(entry.Message);
   }
}
else
{
   MessageBox.Show("There are no entries in the log.");
}
```

Testing your Code

In this section, you will use Server Explorer to verify the results of your code.

Launching Server Explorer

1. From the **View** menu, access Server Explorer.
2. Expand the node for your current server, and then expand the **Event Logs** node beneath it.

> **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features. In this case, you can use the Windows Event Viewer instead to view the results of your application.

Build and run your application

1. Save your files and press **F5** to build and launch your project. The form appears with the eight buttons you created.
2. Click the **Create Custom Log** button.

> **Note** You must have appropriate privileges to the server on which your application runs in order to create Windows event logs. If you receive a security error at this point, see your system administrator.

3. Return to the product, while still in run mode, and right-click the **Event Logs** node in Server Explorer.
4. Click **Refresh**.
5. Verify that the **NewLog1** log now appears in the **Event Logs** node.

To test creating, deleting, and verifying custom logs

1. Return to your running form, and click the **Verify Log Exists** button.

   A prompt should appear with the text set to "True."

2. Click the **Delete Log** button, and then click the **Verify Log Exists** button again.

   This time, the prompt should say "False."

3. Click the **Create Custom Log** button again to recreate the log.

To test writing entries to and reading entries from the custom log

1. In the form, click the **Write Entry** button.
2. Access Server Explorer, and expand the **NewLog1** log.

   > **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

3. Expand the **Source1** node beneath it.

   You should now see that two entries have been added to the log. One will have an icon indicating that it is an informational entry, and one will have an icon indicating that it is an error.

4. Return to the form, and click the **Read Entry** button.

   You will receive two prompts: one containing the informational entry and one containing the error entry.

   > **Note** If you clicked the **Write Entry** button multiple times, you will have received more prompts.

To test clearing the log

1. In the form, click the **Clear Log** button.
2. In Server Explorer, right-click the **NewLog1** node, and then click **Refresh**.

   You should now see that the log no longer contains entries.

To test removing the source string

1. In the form, click the **Remove Event Source** button.
2. Click the **Verify Source** button. You should receive a prompt that says "False" to indicate that the source **Source1** no longer exists.
3. Click the **Write Entry** button.

   > **Note** This action will allow you to write entries to the log, because the **WriteEntry** method will set the source if it does not currently exist.

4. In Server Explorer, right-click the **NewLog1** node, and then click **Refresh**. You should see two entries in the log.
5. Click the **Verify Source** button again. You should receive a prompt that says "True" to indicate that the source **Source1** exists.
6. Optionally, you may want to click the **DeleteLog** button when you are through testing. This will remove the log **NewLog1** and the source **Source1** so that there are no permanent changes to your system's configuration.

Monitoring Windows Services

You can use the **ServiceController** component to interact with the Windows services on your local computer or on any computer to which you have access. The **ServiceController** component allows you to perform administrative tasks such as starting, stopping, and pausing services; to retrieve lists of available services; and to call custom commands on the service.

In This Section

Introduction to Communicating with Existing Services
Gives directions for using the **ServiceController** component to interact with an existing service.
Creating ServiceController Component Instances
Gives directions for creating and configuring **ServiceController** components.
Performing Administrative Tasks on Services
Gives directions for starting, stopping, and pausing your service through the methods available on the **ServiceController** component.
Retrieving Lists of Services
Gives directions for returning lists of services on a specific computer.

Related Sections

Windows Service Applications
Provides links to topics about working with Windows services.
Introduction to Windows Service Applications
Provides an overview of the important concepts about Windows services.

Introduction to Communicating with Existing Services

You can use the **ServiceController** component to connect to and control the behavior of existing services. When you create an instance of the **ServiceController** component, you set it to interact with a specific Windows service. You can then use the component instance to start, stop, and otherwise manipulate the service. For example, you might create a **ServiceController** component and use it with a **Timer** component to start and stop a service based on a timed interval.

You can do several useful things with the **ServiceController** component. For example:

- You can start and stop the service to which you are connected, pause it, or perform any of the other administrative actions to which the service is capable of responding. For more information, see Performing Administrative Tasks on Services.
- You can query various properties of the service with which the component interacts and retrieve the property values. For example, you might determine whether the service can be stopped, paused, and continued by retrieving the value of the **CanStop** and **CanPauseandContinue** properties.
- You can return a list of the services that exist on a particular computer.
- You can specify a custom command to call on your service. For more information on custom commands, see MSDN Online.

The **ServiceController** component actually passes its requests for actions to the Services Control Manager, rather than to the service itself. The Services Control Manager then stops, starts, or pauses the service or performs other actions as specified. After the **ServiceController** has passed the request on to the Services Control Manager, it returns; it does not wait for the Services Control Manager to pass the request on to the service. Because of this, you should handle exceptions within the service class itself rather than in the **ServiceController** class.

> **Note** In general, you should not add a **ServiceController** component to a Windows Service application if your intent is for that component to manipulate the service contained in the same project. Code within the project that creates a service cannot be used to control the service; it must be controlled from another context.

See Also

Creating ServiceController Component Instances | Performing Administrative Tasks on Services | Retrieving Lists of Services

Creating ServiceController Component Instances

You can use the **ServiceController** component to connect to and control the behavior of existing services. When you create an instance of the **ServiceController** class, you set its properties so that it interacts with a specific Windows service. You can then use the class to start, stop, and otherwise manipulate the service.

You will most likely use a **ServiceController** in an administrative capacity. For example, you might create a Windows or ASP .NET Web application that sends custom commands to a service via a **ServiceController** component instance. This would be useful because the Services Control Manager does not support custom commands.

There are several ways you can create an instance of the **ServiceController** component:

- You can drag an instance of the **ServiceController** component from the **Components** tab of the **Toolbox** to a form or other designer.
- You can add a **ServiceController** component to your designer from Server Explorer
- You can create an instance of the **ServiceController** class in code.

After you create an instance of **ServiceController**, you must set two properties on it to identify the service with which it interacts: the machine name and the name of the service you want to control.

> **Note** By default, **MachineName** is set to the local computer, so you do not need to change it unless you want to set the component instance to point to another computer.

To create and configure a ServiceController component from Server Explorer

1. In Server Explorer, add the server you want if it is not already listed. For more information, see Accessing and Initializing Server Explorer.

   > **Note** The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

2. Expand the **Services** node, and then locate the service on which you want to perform administrative tasks.
3. Right-click the name of the service, and click **Add to Designer**.

   A **ServiceController** component appears in your project, configured to interact with the selected service.

To create and configure a ServiceController component from the Toolbox

1. Access the **Components** tab of the **Toolbox**.
2. Select the **ServiceController** icon and drag it to the designer surface for your form or component.
3. Set the following properties.

Property	Setting
MachineName	The name of the computer on which the service exists, or "." for the local computer.
ServiceName	The name of the service with which you want to interact.

> **Tip** You can use **Server Explorer** to see what the **ServiceName** should be set to for any given service. Select the service in which you're interested in **Server Explorer**, and the **ServiceName** for it appears in the **Properties** window.

To programmatically create and configure a ServiceController component

1. Create an instance of the **ServiceController** class in your code.
2. Set the **MachineName** and **ServiceName** properties to indicate the service you want to control.

   The following example shows how to create a **ServiceController** component that interacts with the IIS Admin service on the local computer. The component then queries the service associated with the controller to determine if it can accept Stop commands, and if so, issues the command. This example is part of a Windows project in which a form with various buttons is used to start, stop, and otherwise manipulate the service. Each time a button is clicked, the condition is evaluated and status information is displayed in a label control.

   > **Note** Before these samples will run, you must add a reference to **System** and **System.ServiceProcess** DLLs and include an **Imports** or **Using** statement for the both namespaces.

```
' Visual Basic
Sub Main()
   Dim myController As _
      New System.ServiceProcess.ServiceController("IISAdmin")

   If myController.CanStop Then
      Debug.WriteLine(myController.ServiceName & " can be stopped.")
   Else
      Debug.WriteLine(myController.ServiceName & " cannot stop.")
   End If
End Sub

// C#
public static void Main(string[] args)
{
   System.ServiceProcess.ServiceController myController =
      new System.ServiceProcess.ServiceController("IISAdmin");
   if (myController.CanStop)
   {
      System.Diagnostics.Debug.WriteLine(
         myController.DisplayName + "  can be stopped.");
   }
   else
   {
      System.Diagnostics.Debug.WriteLine(
         myController.DisplayName + "  cannot stop.");
   }
}
```

Introduction to Communicating with Existing Services | Performing Administrative Tasks on Services | Retrieving Lists of Services

Performing Administrative Tasks on Services

You can perform a variety of standard administrative tasks on a service, including starting and stopping it, pausing it, and restarting it. You can perform these tasks in two ways: via Server Explorer, or by calling methods on a **ServiceController** component instance that has been connected to an existing service.

Generally, the service author writes code that customizes the action associated with a specific task. For example, a service can contain code to respond to an **OnPause** command. In that case, the custom processing for the Pause task is carried out before the service is paused. For information on defining functioning for the service, see Creating Windows Services.

The particular tasks that are available for a service depend on its properties; for example, you can set the **CanStop** property for a service to **false**. This renders the Stop command unavailable on that particular service; if you try to stop the service from Server Explorer, the necessary menu item appears dimmed. If you try to stop the service from code, the system raises an error: "Failed to stop <servicename.>"

To perform an administrative task from Server Explorer

1. In **Server Explorer**, add the server you want if it is not already listed. For more information, see Accessing and Initializing Server Explorer.

   Note The Servers node of Server Explorer is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

2. Expand the **Services** node, and then locate the service on which you want to perform administrative tasks.
3. Right-click the name of the service, and click the task you want to perform.

To perform an administrative task programmatically

1. Create an instance of the **ServiceController** class and configure it to interact with the service you want to administer. For more information, see Creating ServiceController Component Instances.
2. Call the appropriate method to start, stop, pause, or continue the service.

   Tip You might want to query the corresponding property for any of these commands to determine if the service will respond to your request; that is, you might want to create a conditional statement that queries the **CanStop** property on the service and determine whether it is set to **true** before you call the **Start** method.

   The following example shows how to evaluate whether a service can accept a given command before issuing the command.

```
' Visual Basic
If myController.CanStop Then
   myController.Stop()
End If

// C#
if (myController.CanStop)
{
   myController.Stop();
}
```

Introduction to Communicating with Existing Services | Creating ServiceController Component Instances | Retrieving Lists of Services | Accessing and Initializing Server Explorer | Creating Windows Services

Retrieving Lists of Services

You can use the **GetServices** method on the **ServiceController** class to retrieve a list of the services on a particular computer. The **GetServices** method returns an array of all of a computer's available services, except for those associated with device drivers. You can retrieve the device driver services using the **GetDevices** method.

For both of these methods, you can either choose a specific computer you're interested in retrieving information about, or you can pass no parameters to retrieve the services on the local computer only.

To retrieve a list of services

1. Create an array of type **ServiceController** to contain the results of your query.
2. Call the appropriate method on the **ServiceController** class and set the results to the array, using one of the following forms:

   - To retrieve non-device driver services from the local computer, call the **GetServices** method without any parameters:

     ```
     ' Visual Basic
     Dim services() As System.ServiceProcess.ServiceController
     services = System.ServiceProcess.ServiceController.GetServices()

     // C#
     System.ServiceProcess.ServiceController[] services;
     services = System.ServiceProcess.ServiceController.GetServices();
     ```

   - To retrieve non-device driver services from a specific computer, call the **GetServices** method and specify the computer from which you want to retrieve information as a string parameter:

     ```
     ' Visual Basic
     Dim services() As System.ServiceProcess.ServiceController
     services = System.ServiceProcess.ServiceController.GetServices( _
        "machinename")

     // C#
     System.ServiceProcess.ServiceController[] services;
     services = System.ServiceProcess.ServiceController.GetServices(
        "machinename");
     ```

   - To retrieve device driver services from the local computer, call the **GetDevices** method without any parameters:

     ```
     ' Visual Basic
     Dim services() As System.ServiceProcess.ServiceController
     services = System.ServiceProcess.ServiceController.GetDevices()

     // C#
     System.ServiceProcess.ServiceController[] services;
     services = System.ServiceProcess.ServiceController.GetDevices();
     ```

   - To retrieve device driver services from a specific computer, call the **GetDevices** method and specify the computer from which you want to retrieve information as a string parameter:

     ```
     ' Visual Basic
     Dim services() As System.ServiceProcess.ServiceController
     services = System.ServiceProcess.ServiceController.GetDevices( _
        "machinename")

     // C#
     System.ServiceProcess.ServiceController[] services;
     services = System.ServiceProcess.ServiceController.GetDevices(
        "machinename");
     ```

The following code shows how to retrieve a set of services on the local computer and display information about each of them in a listbox. Note that the **GetServices** function returns an array of **ServiceController** objects. Each **ServiceController** returned represents one service on the computer being queried:

```
' Visual Basic
Sub ListServices()
   Dim ListBox1 As ListBox

   Dim services() As System.ServiceProcess.ServiceController
   Dim i As Integer
   services = System.ServiceProcess.ServiceController.GetServices()
   ListBox1.Items.Clear()
   For i = 0 To services.Length - 1
      ListBox1.Items.Add(services(i).ServiceName)
   Next
End Sub

// C#
private void ListServices()
{
   ListBox listBox1 = null;

   System.ServiceProcess.ServiceController[] services;
   services = System.ServiceProcess.ServiceController.GetServices();
   listBox1.Items.Clear();
   for (int i = 0; i <  services.Length; i++)
   {
      listBox1.Items.Add(services[i].ServiceName);
   }
}
```

Introduction to Monitoring and Managing Windows Processes

You can use the **Process** component to accomplish most Windows process management tasks quickly and easily. You can use this component to work with processes on either local or remote computers. On a local computer, you can start and stop a process and also query it for specific types of information, including the names of the modules it has loaded, the time it was started, the number of handles it is consuming, and the set of its threads. On a remote computer, you cannot start or stop a process, but you can query existing processes for information.

To work with processes in your classes, you add an instance of the **Process** component to the class. This enables your class to access processes on the servers in your enterprise, and also to start and stop new processes. Other components in your application can call the **Process** component if it is necessary for them to start a new process or manipulate an existing process.

The PerformanceCounter and EventLog components may be better suited for monitoring the system performance. For more information, see Monitoring Performance Thresholds and Logging Application, Server, and Security Events.

Restrictions

Security issues require you to have sufficient access rights on the target computer to run code before attempting to stop processes or retrieving process property information. Any attempt to perform these tasks without the proper access authorization will result in an exception error.

See Also

Securability | Creating and Binding to Processes | Binding to Existing Processes | Creating Process Components | Starting Processes | Stopping Processes | Monitoring Performance Thresholds | Creating and Removing Custom Event Logs

Creating and Binding to Processes

You can use the **Process** component to bind to any running process to which you have rights. After the component has been bound to a target process, you can perform several tasks including stopping the process and viewing process statistics. For example, if a **Process** component has been bound to a process, it will store the starting and stopping time of the target process. You can take this information from the component's properties and assigned them to variables for later use in maintenance applications.

In This Section

Creating Process Components
Gives directions for creating **Process** components.
Binding to Existing Processes
Explains how to bind components to existing processes.

Related Sections

Starting Processes
Describes how to use the **Process** component to start processes on your computer.
Stopping Processes
Describes how to use the **Process** component to stop processes currently running on your computer.
Retrieving Information About Processes
Explains how to use the **Process** component to retrieve property information about processes on your computer.

Creating Process Components

You create instances of the **Process** component to act as a connection between your application and the processes on a computer. Once you bind a **Process** component instance to an individual process, you can use it to stop or retrieve information about the target process. You can use these methods to create applications that monitor and maintain individual processes or perform actions on a group of processes.

To create an instance of the Process component from the Toolbox

1. Drag the **Process** component from the **Components** tab of the Toolbox to the project.

   The component will reside in the component tray of the designer, located at the bottom of the design surface, and will not be visible to the end user.

2. Right-click the component and select **Properties** from the shortcut menu.
3. Expand the **StartInfo** section of the component's property page and set any of the starting properties you require. For more information, see ProcessStartInfo Members.

To create an instance of the Process component programmatically

1. Create an instance of the **Process** component class in code.

```
' Visual Basic
Dim myProcess as New Process()

// C#
using System.Diagnostics;
Process myProcess = new Process();
```

2. Call **Start** to start a new process. For more information, see Starting Processes.

See Also

ProcessStartInfo Members | Starting Processes | Stopping Processes |
Introduction to Monitoring and Managing Windows Processes

Binding to Existing Processes

You can use the **Process** component as a connection between your application and the processes on your computer. You bind to an existing process by using the GetProcessesByName method to return an array of processes (in the form of Process component instances) associated with each running instance of the specified file name. The first element of the array will be the first instance of the running process that the method finds. If there is only one instance of the process, the index of 0 can be used to reference the single instance of the process. You can use each of these returned instances to manipulate the processes with which they are associated.

To bind to an existing process

1. Create an instance of the **Process** component. For more information, see Creating Process Components.
2. Declare an empty array of the type **Process** to hold the array of **Process** components.

```
' Visual Basic
Dim myProcesses() as Process

// C#
Process[] myProcesses;
```

3. Fill the process array by calling the GetProcessesByName or GetProcessById methods and use the returning value to populate the process array.

   The following example shows how to call the **GetProcessesByName** method to add Notepad.exe to the process array.

```
' Visual Basic
myProcesses = Process.GetProcessesByName("Notepad")

// C#
myProcesses = Process.GetProcessesByName("Notepad");
```

4. Use the indexed property value to manipulate a single process in the array.

```
' Visual Basic
' Closes the first instance of Notepad in the process array.
myProcesses(0).CloseMainWindow()

// C#
// Closes the first instance of Notepad in the process array.
myProcesses[0].CloseMainWindow();
```

Managing Processes

You can use the **Process** component to start and stop processes and to retrieve information about your running processes on a computer. For example, you might use an instance of the **Process** component to determine whether a process had stopped responding. If the value returned true, you could have the component force the process to stop or prompt the user with the information and offer a choice of options.

You can use the **Process** component to create applications that allow you to view and manipulate processes and their property values. The topics in this section cover the various tasks associated to managing process using the **Process** component.

In This Section

Starting Processes
Gives instructions on how to use the **Process** component to start processes.
Stopping Processes
Explains how to use the **Process** component to stop running processes.
Determining If a Process Is Responding
Gives instructions on how to use the **Process** component to determine if a process has stopped responding to user input.
Determining If a Process Has Exited
Describes how to use the **Process** component to determine if a process has exited.
Viewing Running Processes
Gives instructions on how to use the **Process** component to view a list of all processes currently running on a computer.
Waiting for Processes to Complete Actions
Describes how to find out if a process has completed an action.

Walkthrough: Managing a Windows Process
Gives step-by-step instructions for managing Windows processes.

Starting Processes

You can use the **Process** component to start processes on your system by calling the Start method. Before you call Start, you must specify the file name of the process to start by setting the FileName property to either the fully qualified path to the target process, or in the case of qualified Windows applications such as Notepad, simply the process name.

You can set the **FileName** property at design time, using the Properties window, or at run time by using a value of the **StartInfo** enumeration. If you set the file name at run time, you can do one of the following:

- Set the appropriate value of the **StartInfo** enumeration and then call **Start**, or
- Call the static form of the **Start** method and specify **FileName** as a parameter. Use this approach if you do not need to set any other starting parameters; you cannot set any other opening arguments in this method.

To start a process at run time using the StartInfo properties

1. Set the starting information by exposed by the **StartInfo** property.
2. Call the **Start** method of the **Process** component.

The following example shows how to open Notepad in a maximized window.

```
' Visual Basic
Dim myProcess as New Process()
myProcess.StartInfo.FileName = "Notepad.exe"
myProcess.StartInfo.WindowStyle = ProcessWindowStyle.Maximized
myProcess.Start()

// C#
Process myProcess = new Process();
myProcess.StartInfo.FileName = "Notepad";
myProcess.StartInfo.WindowStyle = ProcessWindowStyle.Maximized;
myProcess.Start();
```

To start a process at run time by passing the FileName parameter

- Call the **Start** method, entering the **FileName** parameter as a string expression.

```
' Visual Basic
myProcess.Start("Notepad.exe")

// C#
Process myProcess = Process.Start("Notepad");
```

See Also

Creating Process Components | Managing Processes | Introduction to Monitoring and Managing Windows Processes

Stopping Processes

There are two methods you can use to stop a process with a **Process** component. The method you use depends on the type of process being stopped:

- If the process has a graphical user interface, call the CloseMainWindow method. This method sends a close request to the main window of the process and behaves in the same manner as selecting the Close command from the user interface. Using this method gives the target program a chance to prompt the user to save any unsaved data during the cleanup operation.
- If the process does not have a user interface, call the Kill method.

> **Caution** Calling the **Kill** method will stop the process immediately without prompting to save changed data. Any unsaved data will be lost.

If you want the component to be notified when the operating system has shut down a process, you must set the **EnableRaisingEvents** property to **true**. The **EnableRaisingEvents** property is used in asynchronous processing to notify your application that a process has exited. For more information, see Process.EnableRaisingEvents Property.

To stop a process

1. Call the GetProcessesByName method to retrieve the process you want to stop.

   For more information, see Binding to Existing Processes.

2. Call one of the following methods:

   - If the process has a user interface, call the **CloseMainWindow** method.
   - If the process is windowless, call the **Kill** method.

   The following example shows how to call the **CloseMainWindow** method to close all instances of Notepad currently running on a local computer:

```
' Visual Basic
Dim myProcesses() as Process
Dim myProcess as Process
' Returns array containing all instances of "Notepad".
myProcesses() = Process.GetProcessesByName("Notepad")
For Each myProcess in myProcesses
   myProcess.CloseMainWindow()
Next

// C#
Process[] myProcesses;
// Returns array containing all instances of Notepad.
myProcesses = Process.GetProcessesByName("Notepad");
foreach(Process myProcess in myProcesses){
    myProcess.CloseMainWindow();
}
```

See Also

Managing Processes | Binding to Existing Processes | Introduction to Monitoring and Managing Windows Processes

Determining If a Process Is Responding

You can use the Responding property to determine if the user interface of a process is responding. When you attempt to read the **Responding** property, a request is sent to the user interface of the target process. If there is an immediate response, the return property value is **true**; a **false** property value is returned if there is no response from the interface. This property is useful if you need to force a frozen application to close.

To determine if a process is responding

1. If the process was not started with a component, associate a **Process** component to the target process. For more information, see Binding to Existing Processes.
2. Read the **Responding** property by calling the **Responding** method.
3. Determine a course of action to take depending on the property value.

The following example shows how to determine if Notepad is responding. If the **Response** property is **true,** call the **CloseMainWindow** method to close the application. If the **Response** property is **false**, the **Kill** method is called to force the process to close.

```
' Visual Basic
Dim myProcesses() as Process
myProcesses = Process.GetProcessesByName("Notepad.exe")
' Tests the Responding property for a True return value.
If myProcesses(0).Responding Then
   myProcesses(0).CloseMainWindow()
Else
   ' Forces the process to close if the Responding value is False.
   myProcesses(0).Kill()
End If

// C#
Process[] notepads;
notepads = Process.GetProcessesByName("Notepad.exe");
// Test to see if the process is responding.
if (notepads[0].Responding)
{
   notepads[0].CloseMainWindow();
}
else
{
   notepads[0].Kill();
}
```

Retrieving Information About Processes | Starting Processes | Managing Processes | Stopping Processes | Binding to Existing Processes

Determining If a Process Has Exited

You can use the HasExited property to determine if the process associated to a **Process** component has stopped running. The property value returns **true** if the process is closed and **false** if the process is still running.

> **Note** This value is only returned for processes that are started by a **Process** component.

The **Process** component does not need to close the associated process to obtain the **HasExited** property. Administrative information such as the **HasExited** and **ExitTime** properties are stored regardless of the way the associated process was closed. The information is stored even if the user closes the process by selecting the Close command in its interface. This information is useful if you want to make sure all processes started with your **Process** components close when you exit an application.

To determine if a process has exited

- Read the **HasExited** property of the **Process** component that was used to open the process.

The following example shows how to use the **HasExited** property to determine if the process associated with a **Process** component called Process1 has been closed. If it is open, call **CloseMainWindow** to close the application.

```
' Visual Basic
If Not Me.notepad.HasExited Then
   ' If the process is still running, close it.
   Me.notepad.CloseMainWindow
End If

// C#
if (!notepad.HasExited) {
   notepad.CloseMainWindow();
}
```

Viewing Running Processes

When working with processes on a system, it is sometimes necessary to view all processes that are running at a given time. For example, if you want to create an application that gives you the functionality of stopping processes, you must first see which processes are running. You could fill a list box with the process names and select which process to perform any other actions on.

To view running processes

1. Declare an empty array of the type **Process**.
2. Fill the empty array with the return value from the GetProcesses method.
3. Iterate through the process array using the indexed value to obtain the process name of each process in the array and write it to a console.

The following example shows how to call the **GetProcesses** method of a **Process** component to return the process array and writes the **ProcessName** value to a console.

```
' Visual Basic
Dim myProcesses() as Process
Dim myProcess As Process
myProcesses = Process.GetProcesses()
' Iterate through the process array.
For Each myProcess in myProcesses
   Console.WriteLine(myProcess.ProcessName)
Next

// C#
Process[] myProcesses = Process.GetProcesses();
foreach(Process myProcess in myProcesses)
{
   Console.WriteLine(myProcess.ProcessName);
}
```

Waiting for Processes to Complete Actions

A process is said to be idle when its main window is waiting for input from the system. In order to test the process for its idle state, you must first bind a **Process** component to it. You can call the WaitForInputIdle method before having the target process perform an action.

The **WaitForInputIdle** method instructs a **Process** component to wait for the associated process to enter an idle state. The method is useful, for example, when your application waits for a process to finish creating its main window before communicating with that window. The **WaitForInputIdle** method only works with processes that have a user interface.

To wait for a process to complete an action

1. Associate an instance of a **Process** component to a process you want to start. For more information, see Starting Processes.
2. Start the process by calling the **Start** method.
3. Call the appropriate **WaitForInputIdle** method:

   - **WaitForInputIdle()** - instructs the **Process** component to wait indefinitely for the associated process to enter an idle state.
   - **WaitForInputeIdle(Int32) -** instructs the **Process** component to wait the specified number of milliseconds for an associated process to enter an idle state.

The following example shows how to call the **WaitForInputIdle** method to wait for Notepad to complete loading before assigning its modules property to an empty array.

```
' Visual Basic
Dim myProcess as New Process()
myProcess.Start("Notepad.exe")
myProcess.WaitForInputIdle()

// C#
Process myProcess;
myProcess = Process.Start("Notepad");
myProcess.WaitForInputIdle();
```

Retrieving Information About Processes

You can use the **Process** component to retrieve property information about a process. The component can retrieve several useful categories of information from the properties of the target component and store the values in its own cached properties.

Investigating Memory Usage for Processes

If you need to view memory statistics for a process, the **Process** component provides six memory-usage properties that can be accessed at run time. Each property provides a different statistic for memory allocation.

To investigate memory usage for a process

1. Bind a process component instance to the process. For more information, see Binding to Existing Processes.
2. If the property cache needs to be refreshed, call the **Refresh** method. For more information, see Refreshing Process Component Properties.
3. Read the memory-usage property you want by referencing the appropriate property.

Property	Returns
PrivateMemorySize	The number of bytes that the associated process has allocated that cannot be shared with other processes.
PeakVirtualMemorySize	The maximum amount of virtual memory that the process has requested.
PeakPagedMemorySize	The maximum amount of memory that the associated process has allocated that could be written to the virtual paging file.
PagedSystemMemorySize	The amount of memory that the system has allocated on behalf of the associated process that can be written to the virtual memory paging file.
PagedMemorySize	The amount of memory that the associated process has allocated that can be written to the virtual memory paging file.
NonpagedSystemMemorySize	The amount of memory that the system has allocated on behalf of the associated process that cannot be written to the virtual memory paging file.

The following example shows how to use the **Process** component to read the **PrivateMemorySize** property for Notepad and assign the returned property value to NotepadMemory. The value is then displayed in a console. Because Component1(0) is a new instance of the **Process** component, the property cache does not need to be refreshed.

```
' Visual Basic
Dim NotepadMemory as Integer
Dim component1() as Process
component1 = Process.GetProcessesByName("Notepad.exe")
NotepadMemory = component1(0).PrivateMemorySize
Console.WriteLine("Memory used: " & NotepadMemory & ".")

// C#
int memory;
Process[] notepads;
notepads = Process.GetProcessesByName("Notepad.exe");
notepadMemory = notepads[0].PrivateMemorySize;
Console.WriteLine("Memory used: {0}.", notepadMemory);
```

Retrieving Information About Processes | Binding to Existing Processes | Introduction to Monitoring and Managing Windows Processes

Investigating Thread Usage for Processes

You can view the process threads by reading the Threads property value of the **Process** component. The return value is a collection of the type **ProcessThread** that represents the operating system threads currently running in the process. You can then iterate through the array to view individual thread properties using the Array(Index) property. The primary thread is not necessarily the thread at index 0 of the array.

To investigate thread usage for a process

1. If the process was not started by a **Process** component, associate a **Process** component to the desired process. For more information see Binding to Existing Processes.
2. Assign the **Threads** property value of the process to an empty collection variable of the type **ProcessThread**.
3. Iterate through the array index to view properties for a single **Thread**.

The following example shows how to read the **Threads** property of Notepad and assign the value to an empty array. The **Thread.BasePriority** value of the first thread in the **ProcessThread** array is then read and displayed in a textbox named TextBox1.

```
' Visual Basic
Dim myCollection as ProcessThreadCollection
Dim myProcesses() as Process
' Create an instance of the Process Component and associate
' it to the target process.
myProcesses() = Process.GetProcessesByName("Notepad.exe")
' Read the Process.Threads property and assign it to the empty array.
myCollection = myProcesses(0).Threads
' Read desired ProcessThread property.
Me.Textbox1.Text = myCollection(0).BasePriority.ToString()

// C#
ProcessThreadCollection threads;
Process[] notepads;
// Retrieve the Notepad processes.
notepads = Process.GetProcessesByName("Notepad");
// Read the Process.Threads property.
threads = notepads[0].Threads;
// Read desired ProcessThread property.
This.Textbox1.Text = threads[0].BasePriority.ToString()
```

See Also

Introduction to Monitoring and Managing Windows Processes | Binding to Existing Processes | Retrieving Information About Processes | Managing Processes | Creating Process Components

Investigating Libraries Loaded by Processes

The **Modules** property of the **Process** component provides access to the loaded libraries for a process. The **Modules** property returns a collection of the type **ProcessModules**, which includes all loaded libraries for the target process. You can then iterate through the collection using the **Indexed** property to look at individual libraries.

To investigate library usage for a process

1. If the target process was not started by a **Process** component, bind a new instance of a **Process** component to the process. For more information, see Binding to Existing Processes.
2. Declare an empty array of type **ProcessModules** to hold the module collection.
3. Assign the **Modules** property to the **ProcessModules** variable. This populates the **ProcessModules** array with the modules from the target module.
4. Iterate through the **ProcessModules** array by using the **Array(Index)** property to view and manage individual libraries.

The following example shows how to return all loaded libraries for Microsoft Word and then pass the library name to a list box on Form1:

```
' Visual Basic
Dim WordProcesses() as Process
Dim WordModules as ProcessModuleCollection
Dim aModule as ProcessModule
WordProcesses = Process.GetProcessesByName("WinWord")
' Populate the module collection.
WordModules = WordProcesses(0).Modules
' Iterate through the module collection.
For each aModule in WordModules
   Form1.Listbox1.Items.Add(aModule.ModuleName)
Next

// C#
Process[] wordapps;
ProcessModuleCollection modules;
wordapps = Process.GetProcessesByName("WinWord");
// Populate the module collection.
modules = wordapps[0].Modules;
// Iterate through the module collection.
foreach (ProcessModule aModule in modules)
{
   Form1.Listbox1.Items.Add(aModule.ModuleName);
}
```

Managing Processes | Retrieving Information About Processes | Creating Process Components | Binding to Existing Processes

Refreshing Process Component Properties

A **Process** component's properties are stored in a cache. The properties are used to store the property values of the process that the component is bound to.

The properties are not filled until you make the first property request from the process. At that time the component fills its cached properties with the property values of the process that it is bound to. The component does not renew this information when subsequent property value requests are made.

To view current property values, you must call the **Refresh** method of the **Process** component before requesting property values of the process. When you call the **Refresh** method, the values in the component's properties are replaced with the current data from the properties of the target process.

To refresh Process component properties

1. Create an instance of the process programmatically or by adding a **Process** component to the project in design view. For more information, see Binding to Existing Processes.
2. If any changes have occurred to the process properties prior to retrieving property information, call the **Refresh** method.
3. Set properties to read the appropriate process information and assign the returned value to a variable.

The following example shows how to open an instance of Notepad and then calls the **Refresh** method to update the component's properties. The code then reads the updated **WorkingSet** property of the component to return the total amount of memory allocated for the associated process. The updated property value is then written to a console screen six times in two-second intervals. The console stays open for five seconds after the procedure is finished.

```
' Visual Basic
Dim Notepad As New Process()
Dim myProcess As Process
Dim i As Integer
Notepad.Start("Notepad.exe")
For i = 0 to 5
   ' Forces the Process component to get a new set of property values.
   Notepad.Refresh
   ' Writes the property value to the console screen.
   Console.WriteLine(Notepad.WorkingSet)
   ' Waits two seconds before running the next loop.
   System.Threading.Thread.Sleep(2000)
Next
' Closes Notepad and waits 5 seconds before closing the console screen.
Notepad.CloseMainWindow()
System.Threading.Thread.Sleep(5000)

// C#
Process notepad;
notepad = Process.Start("Notepad");
for (int i = 0;i < 5; i++)
{
   // Forces the Process component to get a new set
   // of property values.
   notepad.Refresh();
   // Writes the property value to the console screen.
   Console.WriteLine(notepad.WorkingSet.ToString());
   // Waits two seconds before running the next loop.
   System.Threading.Thread.Sleep(2000);
}
// Closes Notepad and waits 5 seconds before closing
// the console screen.
notepad.CloseMainWindow();
System.Threading.Thread.Sleep(5000);
```

Walkthrough: Managing a Windows Process

The procedures in this topic walk you through the steps involved in creating a process, responding when a process stops, and stopping processes. In the first section, you will create a Windows application with **Button** controls to start and stop a **Notepad** process. You will start several instances of **Notepad** individually and then stop them as a group. In the second section, you will create a console application that enumerates the processes running on your computer.

For more information on using the **Process** component to interact with system processes, see Introduction to Monitoring and Managing Windows Processes.

To create your application

1. From the **New Project** dialog box, create a Visual Basic or Visual C# **Windows Application**.
2. With the Form1 designer open, click the **Windows Forms** tab in the Toolbox, and then add two buttons to the form.
3. In the Properties window, change the following properties:

Control	Property	Value
Button1	Name	**ButtonStart**
	Text	**Start Process**
Button2	Name	**ButtonStop**
	Text	**Stop Process**

4. Click the **Component** tab in the Toolbox, and then drag an instance of the **Process** component to the designer surface.
5. Name the component **myProcess**.

To start the Notepad.exe process

1. In the Properties window for the **Process** component instance, expand the **StartInfo** property, and set the **FileName** property to **notepad.exe**.
2. Double-click the **Start** button to access the Code Editor, and then add the following code to the **ButtonStart_Click()** event:

```
' Visual Basic
myProcess.Start

// C#
myProcess.Start();
```

3. Save all files, and then build and run the application.
4. Click the **Start Process** button a few times. You will see separate instances of Notepad for each click.

   Security Note If you are running in a partial-trust context, the process might throw a SecurityException Class exception due to insufficient privileges. For more information, see Code Access Security Basics.

5. Close the individual **Notepad** applications.
6. Close the **Form1** application.

To close all current instances of the Notepad.exe process

1. From Design view, double-click the **Stop** button to access the **ButtonStop_Click()** procedure.
2. Add the following code to close the current instances of Notepad.

```
' Visual Basic
Private Sub ButtonStop_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles ButtonStop.Click
   Dim myProcesses() As Process
   Dim instance As Process
   myProcesses = Process.GetProcessesByName("Notepad")
   For Each instance In myProcesses
      instance.CloseMainWindow()
   Next
End Sub
```

```
// C#
private void ButtonStop_Click(object sender, System.EventArgs e)
{
   System.Diagnostics.Process[] myProcesses;
   myProcesses =
      System.Diagnostics.Process.GetProcessesByName("Notepad");
   foreach (System.Diagnostics.Process instance in myProcesses)
   {
      instance.CloseMainWindow();
   }
}
```

3. Save all files, and then build and run your application.
4. Start several instances of Notepad by clicking the **Start Process** button.
5. Click the **Stop Process** button to immediately close all running instances of Notepad.
6. Close the **Form1** application.

To configure the component to wait for the Notepad process to finish running

In this procedure, you will freeze your code until the process finishes.

1. Access the Code Editor for Form1.
2. Modify the code by adding a line of code to cause a pause before closing each window.

```
' Visual Basic
Private Sub ButtonStop_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles ButtonStop.Click
   Dim myProcesses() As Process
   Dim instance As Process
   myProcesses = Process.GetProcessesByName("Notepad")
   For Each instance In myProcesses
      instance.WaitForExit(3000)
      instance.CloseMainWindow()
   Next
End Sub

// C#
private void ButtonStop_Click(object sender, System.EventArgs e)
{
   System.Diagnostics.Process[] myProcesses;
   myProcesses =
      System.Diagnostics.Process.GetProcessesByName("Notepad");
   foreach (System.Diagnostics.Process instance in myProcesses)
   {
      instance.WaitForExit(3000);
      instance.CloseMainWindow();
   }
}
```

3. Save all files, and then build and run the application.
4. Start several instances of Notepad by clicking the **Start Processes** button.
5. Click the **Stop Processes** button to close the processes as before.

   You will notice that the application now waits 3 seconds for each process to stop before closing the next instance of the process.

6. Close the **Form1** application.

In this portion of the walkthrough, you will create a new console application that will retrieve and list the processes on the local computer.

To enumerate the processes on your computer

1. Create a new **Console Application** project.
2. In Solution Explorer, right-click the project and select **Properties**.
3. On the **General** tab of the **Property Pages** dialog box, set the **StartupObject** property for your project to **Sub Main**. Note that the **StartupObject** in C# will be the class name which contains the **Static Main Method**.
4. Open the Code Editor for the module, and then add the following code to your module to enumerate the processes on your computer:

```
' Visual Basic
Shared Sub Main()
   Dim processes() As Process
   Dim instance As Process
   Dim process As New Process()
   processes = process.GetProcesses
   For Each instance In processes
      Console.WriteLine(instance.ProcessName)
   Next
   System.Threading.Thread.Sleep(5000)
End Sub

// C#
static void Main()
{
   System.Diagnostics.Process[] processes;
   processes = System.Diagnostics.Process.GetProcesses();
   foreach (System.Diagnostics.Process instance in processes)
   {
      Console.WriteLine(instance.ProcessName);
   }
   System.Threading.Thread.Sleep(5000);
}
```

5. Save all files, and then build and run your application.

   The application will open a console window containing a list of all processes currently running on your computer. Calling **Thread.Sleep** pauses the console for 5 seconds before closing it.

   > **Note** You may receive exceptions in these two procedures if you call **GetProcesses** or **GetProcessesByName** and one of the returned processes finishes before you make the next call. In that case, you will receive an exception saying that the process does not exist.

Creating Active Directory Components

The .NET Framework provides two Active Directory component classes: **DirectoryEntry** and **DirectorySearcher**. They are classes of the **System.DirectoryServices** namespace that use the Active Directory Services Interfaces (ADSI) technology. ADSI is the set of interfaces Microsoft provides as a flexible tool for working with a variety of network providers. ADSI gives the administrator the ability to locate and manage resources on a network with relative ease, regardless of the network's size. The topics in this section cover the various tasks and concepts involved in working with Active Directory objects.

Active Directory Services Interface (ADSI): Frequently Asked Questions
Provides answers to common questions about ADSI, including service providers supported.

Introduction to Active Directory Objects

Active Directory Service Interfaces (ADSI) is a programmatic interface for Microsoft Windows Active Directory. It enables your applications to interact with diverse directories on a network, using a single interface. Visual Studio .NET and the .NET Framework make it easy to add ADSI functionality with the **DirectoryEntry** and **DirectorySearcher** components. For an overview of Active Directory, see Active Directory Technology Backgrounder.

Using ADSI, you can create applications that perform common administrative tasks, such as backing up databases, accessing printers, and administering user accounts. ADSI makes it possible for you to:

- Log on once to work with diverse directories. The **DirectoryEntry** component class provides username and password properties that can be entered at runtime and communicated to the Active Directory object you are binding to.
- Use a single application programming interface (API) to perform tasks on multiple directory systems by offering the user a variety of protocols to use. The **DirectoryServices** namespace provides the classes to perform most administrative functions.
- Perform "rich querying" on directory systems. ADSI technology allows for searching for an object by specifying two query dialects: SQL and LDAP. For more information see Searching Active Directory Hierarchies.
- Access and use a single, hierarchical structure for administering and maintaining diverse and complicated network configurations by accessing an Active Directory tree.
- Integrate directory information with databases such as SQL Server. The **DirectoryEntry** path may be used as an ADO.NET connection string provided that it is using the LDAP provider.

Searching Directories

You can use the **DirectorySearcher** class to search and perform queries against an Active Directory hierarchy using the Lightweight Directory Access Protocol (LDAP). You can perform queries based on properties (Rich Query) of an object that is located in a large directory to find a specific object by one or more of its property values. For more information, see Searching Active Directory Hierarchies.

Administering Directories

The **DirectoryEntry** component can be bound to an object in the directory to perform administrative tasks, such as modifying properties or monitoring informational changes. For example, suppose that your company allows employees to place online orders for books needed in their jobs. Spending limits vary depending on the employee's position. When an employee places a book order, the company's tracking application can use a **DirectoryEntry** component to verify information about the employee's position and spending limits. If the limit is exceeded, the **DirectoryEntry** component can retrieve the e-mail address for the employee and his manager and can then send additional information to both of them.

Requirements

Both the **DirectoryEntry** component and **DirectorySearcher** component require that you have the ADSI SDK or ADSI runtime installed on your computer in order to create applications with their functionality. ADSI 2.5 is installed by default with Windows 2000 or Windows XP. If you are using a previous version of Windows, you can install the SDK yourself from the Microsoft Web site.

The following requirements apply to **DirectoryEntry** components:

- To make changes to property values of Active Directory objects, you must have administrative rights to the object you are bound to. For information about Active Directory user rights see your Active Directory documentation in the Windows 2000 help directory.

The following requirements apply to **DirectorySearcher** components:

- **DirectorySearcher** component instances require the LDAP provider to perform rich queries against an Active Directory hierarchy.
- You must have a directory service provider, such as Active Directory or Lightweight Directory Access Protocol (LDAP), installed on your computer for the ADSI APIs to be useful when conducting searches. For more information about the directory services you can use and how to install them, see the Microsoft Web site.

See Also

Walkthrough: Adding Active Directory Objects | Active Directory Technology Backgrounder |

Active Directory Technology Backgrounder

Active Directory is the Windows directory service that provides a unified view of complex networks. It reduces the number of directories and namespaces with which a developer must contend. To use the ADSI technology, client computers must have ADSI 2.5 or later installed on them. ADSI 2.5 is automatically installed with Windows 2000 and therefore does not require installation.

In a typical organization, there are often diverse types of directories in use. These may include Windows NT directories, application-specific directories, and directories of network resources. This variety can cause problems for end users, developers, and administrators. A user may encounter problems while trying to log on to multiple resources. An administrator may face difficulties in maintaining network resources on diverse systems. As a developer, you may need to write an application to seamlessly interact with several different directories.

> **Visual Basic Note** Although you could access Active Directory Services Interfaces (ADSI) in Microsoft Visual Basic version 6.0, programming for it involved a complex series of API calls. Now you can simply use the **DirectoryEntry** component.

Active Directory Basic Concepts

Active Directory provides a straightforward structuring of a complicated network of computers. An Active Directory system is arranged in a hierarchical tree. Each node represents a resource or service available on the network and contains a set of properties that can be retrieved and manipulated.

Directory Service

A directory is an information source used to store information about interesting objects. A telephone directory stores information about telephone subscribers. In a file system, the directory stores information about files. In a distributed computing system or a public computer network such as the Internet, there are many interesting objects: printers, fax servers, applications, databases, and other users. Users want to find and use these objects. Administrators want to manage how these objects are used.

A directory service differs from a directory in that a service is both the information source and the functionality that makes the information available to users. For example, a directory service stores information about objects such as users. That information can be used for identification when communicating with network resources, but also as the definition of where the object fits into the overall hierarchical scheme. *Scope* is the limits defined for searching the tree or subtrees. For more information about namespaces, scopes, containers, and domains, see About ADSI. For more information about the administration and data models, see Active Directory Architecture.

Active Directory Schema

Active Directory schemas define attributes for directory objects in much the same way that database schemas define structures for databases. This schema information is stored with an Active Directory hierarchy to help expedite member searches on large directories. For more information, see Active Directory Schema.

Security

Active Directory provides a variety of security tools such as Secure Sockets Layer and Kerberos encryption to create a flexible security environment for developers. For more information, see Active Directory Security.

Working with Active Directory in Visual Studio or the .NET Framework

The **DirectoryEntry** component makes it easy to access an object from a directory and work with its data and behaviors. When you give the **DirectoryEntry** component a valid directory path in an Active Directory hierarchy, it returns an ADSI COM object that you can manipulate. Examples of ADSI objects include users, computers, services, organizations of user accounts and computers, file systems, and file service operations.

You can use the **DirectoryEntry** component to work with directories in an Active Directory hierarchy in several ways:

- You can search an Active Directory hierarchy to find a particular service or object.
- You can encapsulate a node from a hierarchy and manipulate or query its properties.
- You can add new nodes to the hierarchy.

You can use the **DirectoryEntry** component to automate common administrative tasks, such as adding users and groups, managing printers, and setting permissions on network resources. You can use **DirectoryEntry** components to interact with any resource on any directory system in your enterprise.

ADSI and Active Directory Schema

Active Directory uses a schema to define what information about a network node is accessible. The **DirectoryEntry** and **DirectorySearcher** components use this information to conduct searches and view individual properties of nodes in the directory. Schemas are stored within an Active Directory hierarchy, making searching and accessing a large directory more efficient. Schemas provide a means to create global definitions for object types stored in the directory and are given useful names such as "user," and "computer". The type of information that you would access on a network computer would be different from that of a user in a domain.

The **DirectoryEntry** component also uses Active Directory schemas when creating new objects. You are required to specify a preexisting schema name that the object will be associated to. Microsoft provides example schemas with the ADSI SDK in the MMC folder of the Samples directory.

Providers and Objects

Each type of directory system you can access with the **DirectoryEntry** component has a specific directory protocol (called a *service provider*) that allows you to access and work with that directory's contents. ADSI was created to eliminate the difficulty of switching back and forth between these protocols by enabling developers to access all of the protocols through a single interface.

When you create an instance of a **DirectoryEntry** component, you specify a path for it that indicates the type of provider in use on the system you are accessing and the object to which you want to bind. The following table lists the service providers you can access and the identifiers for each.

Service provider	Path identifier
Windows 2000 or Windows XP	WinNT://path
Lightweight Directory Access Protocol (LDAP)	LDAP://path
Novell NetWare Directory Service	NDS://path
Novell Netware 3.*x*	NWCOMPAT://path

For more information about what constitutes a valid directory path in an Active Directory hierarchy for each type of provider, see Namespaces.

Each service provider makes available to you a different set of objects with associated data and behaviors that you can access and manipulate. These objects correspond to items and resources in the directory tree for that namespace. Many of the providers have objects in common. For example, all of the providers give you access to a group object that represents a group account, and a user object that represents a user account.

For the Windows NT service providers, you can access domains, computers, print queues, and sessions. For the LDAP provider, you can access organizations, locality, and Root DS Entry (rootDSE) objects. The Root DS Entry is a required set of operational attributes that the user can read to find out fundamental characteristics of the directory and the server. The rootDSE is required only for LDAP providers.

Introduction to Active Directory Objects | Creating DirectoryEntry Component Instances |
Walkthrough: Adding Active Directory Objects

Creating DirectoryEntry Component Instances

You create a **DirectoryEntry** or **DirectorySearcher** component instance when you want to interact with the contents of an Active Directory hierarchy in your application. For more information, see Introduction to Active Directory Objects. To use either the **DirectoryEntry** component or the **DirectorySearcher** component, you must add a reference to the **System.DirectoryServices** namespace to your application. For more information, see Adding and Removing References. For more information on creating DirectorySearcher components, see Searching Active Directory Hierarchies.

There are several ways you can create an instance of the **DirectoryEntry** component:

- You can drag an instance of the **DirectoryEntry** component from the Components tab of the Toolbox to a designer.
- You can create an instance of the **DirectoryEntry** component in code.

> **Note** Unlike many of the other components on the Components tab of the Toolbox, **DirectoryEntry** components are not represented in Server Explorer, so you cannot create instances of the component from there.

To create an instance of the DirectoryEntry component in a designer

1. Drag a **DirectoryEntry** object from the **Components** tab of the **Toolbox** to the design surface for your form or component.
2. In the **Properties** window, set the **Path** property for your component to the location in the Active Directory hierarchy for the resource to which you want to bind the component, using this syntax:

```
Provider://providerpath
```

Where	Is
Provider	An indicator of the service provider for the directory to be accessed. The provider identifiers are case-sensitive and must be typed as shown. Must be one of the following values: • LDAP:// • WinNT:// • NDS:// • NWCOMPAT://
ProviderPath	Depending on the type of service provider chosen, the parameters in the provider path vary. For more information, see ADSI System Providers.

For example, the following are valid paths for different types of providers:

```
LDAP://MyDom.fabrikam.com/CN=SomeCN,DC=DEV,DC=SOMEDC,DC=COM,O=Internet
LDAP://CN=SomeCN,DC=DEV,DC=SOMEDC,DC=COM,O=Internet
WinNT://MyDomain/Group
WinNT://MyDomain/MyComputer/aPrinter/
NDS://ndsServer/O=Internet/DC=COM/DC=SOMEDC/DC=DEV/CN=SomeCN
NWCOMPAT://binderyServer/ADivision
```

To create an instance of the DirectoryEntry component programmatically

- Create an instance of the **DirectoryEntry** class in code, passing the path for the object to which you want to bind as a parameter.

  The following example shows how to pass the provider path to your **DirectoryEntry** object:

```
' Visual Basic
Dim myDir As
   New System.DirectoryServices.DirectoryEntry("provider://path")

// C#
System.DirectoryServices.DirectoryEntry myDir =
```

```
    new System.DirectoryServices.DirectoryEntry("provider://path");
```

The following example shows how to create a **DirectoryEntry** component instance in code, initialize it to an LDAP path, and retrieve its name and GUID for display in a form element:

```
' Visual Basic
Dim strpath As String = "LDAP://DC=onecity,DC=corp,DC=fabrikam,DC=com"
Dim myDE As New System.DirectoryServices.DirectoryEntry(strpath)
Dim nameGUID As String
nameGUID = myDE.Name & myDE.Guid.ToString()

// C#
String strpath = "LDAP://DC=onecity,DC=corp,DC=fabrikam,DC=com";
System.DirectoryServices.DirectoryEntry myDE = new
   System.DirectoryServices.DirectoryEntry(strpath);
string nameGuid = myDE.Name + myDE.Guid.ToString();
```

Introduction to Active Directory Objects | Removing Active Directory Nodes | Searching Active Directory Hierarchies | Walkthrough: Adding Active Directory Objects

Modifying Object Properties in an Active Directory Hierarchy

You can use the **DirectoryEntry** class to retrieve a node from an Active Directory hierarchy and modify its property content. An example would be changing an employee's personal information after the employee moves to a different area of the organization. After you modify a node, you must commit your changes in order for them to be saved to the tree. For more information, see Introduction to Active Directory Objects.

Note You must have administrator rights to a directory in order to modify any of its information.

To modify an object in the Active Directory hierarchy

1. Create an instance of the **DirectoryEntry** component, binding it to the known object in the active directory hierarchy with the object's path. For more information, see Creating DirectoryEntry Component Instances.

```
' Visual Basic
Dim User As New System.DirectoryServices.DirectoryEntry( _
   "LDAP://CN=nate sun, CN= users, DC=Sales, DC=CompanyA, DC=COM")

// C#
System.DirectoryServices.DirectoryEntry user =
   new System.DirectoryServices.DirectoryEntry(
   "LDAP://CN=nate sun/CN= users, DC=Sales, DC=CompanyA, DC=COM");
```

2. Make the necessary changes to the object's properties by referring to it by name.

   The following example shows how to change the office telephone number for an employee:

```
' Visual Basic
User.Properties("HomeNumber")(0) = "(425) 555-1212"

// C#
user.Properties["HomeNumber"][0]= "(425) 555-1212";
```

3. Call the CommitChanges method save your modifications to the item in the directory.

```
' Visual Basic
User.CommitChanges()

// C#
user.CommitChanges();
```

Introduction to Active Directory Objects | Searching Active Directory Hierarchies | Walkthrough: Adding Active Directory Objects | Removing Active Directory Nodes

Creating Nodes in an Active Directory Hierarchy

The Active Directory hierarchy can be comprised of several thousand nodes. Each node represents an object, such as a network printer or a user in a domain. Corporate networks constantly change as new employees are hired and objects such as network printers and computers are added. ADSI technology provides ways to programmatically add these objects to the directory tree.

To create a directory entry in the hierarchy, you must use the Children property of the **DirectoryEntry** component. The **Children** collection provides an **Add** method that allows you to add a node to the **Children** collection directly below the parent node that you are currently bound to. To do this, you must specify a name for the new node and the name of a schema template that you wish to associate with the node. For example, you may want to use a schema titled "computer" to add new computers.

To create a node in an Active Directory hierarchy

1. Bind an instance of the **DirectoryEntry** object to the parent directory and call the **Add** method to add a child to the directory. For more information, see Creating DirectoryEntry Component Instances.

```
' Visual Basic
Dim entry As New DirectoryServices.DirectoryEntry("WinNT://DomainName")
entry.Children.Add("NewEntryName", "SchemaNametoUse")

// C#
System.DirectoryServices.DirectoryEntry entry =
   new System.DirectoryServices.DirectoryEntry("WinNT://DomainName");
entry.Children.Add("NewEntryName","NameofSchemaTemplate");
```

Introduction to Active Directory Objects | Searching Active Directory Hierarchies | Walkthrough: Adding Active Directory Objects | Removing Active Directory Nodes | Modifying Object Properties in an Active Directory Hierarchy

Removing Active Directory Nodes

The **DirectoryEntry** component gives the administrator the ability to remove objects within a directory or entire directory subtrees from the hierarchy.

- To remove a child entry from children collection of the current parent directory, call the Remove method. The **Remove** method takes only one argument, the entry name to be removed, and must be used only on an empty container or an object which is not used as a container for a directory tree, such as printers or computer nodes.
- To delete an entry and all of its children, call the DeleteTree method. The **DeleteTree** method deletes the current entry and all of its subtree entries from the hierarchy.

To delete a child entry

- Bind an instance of the **DirectoryEntry** class to the parent directory and call the **Remove** method. For more information, see Creating DirectoryEntry Component Instances.

```
' Visual Basic
Dim entry As New DirectoryServices.DirectoryEntry("WinNT://DomainName")
Dim entryToRemove As DirectoryServices.DirectoryEntry
' Add code here to set entryToRemove to the entry you want to remove.
entry.Children.Remove(entryToRemove)

// C#
System.DirectoryServices.DirectoryEntry entry =
   new System.DirectoryServices.DirectoryEntry("WinNT://DomainName");
System.DirectoryServices.DirectoryEntry entryToRemove = null;
// Add code here to set entryToRemove to the entry you want to remove.
entry.Children.Remove(entryToRemove);
```

To delete an entire subtree

- Bind an instance of the **DirectoryEntry** class to the parent directory and call the **DeleteTree** method. For more information, see Creating DirectoryEntry Component Instances.

```
' Visual Basic
Dim entry As New DirectoryServices.DirectoryEntry("WinNT://DomainName")
entry.DeleteTree()

// C#
System.DirectoryServices.DirectoryEntry entry =
   new System.DirectoryServices.DirectoryEntry("WinNT://DomainName");
entry.DeleteTree();
```

Introduction to Active Directory Objects | Walkthrough: Adding Active Directory Objects | Modifying Object Properties in an Active Directory Hierarchy | Creating DirectoryEntry Component Instances

Searching Active Directory Hierarchies

You can use the **DirectorySearcher** class to search and perform queries against an Active Directory hierarchy using the Lightweight Directory Access Protocol (LDAP). LDAP is the only provider that allows directory searching. An administrator can make alter and delete objects found in the hierarchy. For more information, see Introduction to Active Directory Objects. When you instantiate the **DirectorySearcher** object, you pass it the root you want to search in the bound directory system, an optional filter specifying what you want to retrieve, and an optional list of properties to be retrieved. You can also set properties to determine:

- Whether to cache the search results on the local computer; set this using the **CacheResults** property. When set to **true**, directory information is stored on the local computer.
- How long to spend on the search; set this using the **TimeLimit** property.
- Whether to retrieve property names only or names and values together; set this using the **PropertyNamesOnly** property.
- Whether or not to perform a paged search in which results of a specific size are returned one at a time; set this using the **PageSize** property.
- The maximum number of entries to return by setting the **SizeLimit** property.

> **Note** If the maximum number of returned entries and **TimeLimit** properties exceed limitations set on the server, the server settings will override the component settings.

To search an Active Directory hierarchy

1. Create an instance of the **DirectorySearcher** object and initialize it to the **DirectoryEntry** value that you want to search. Create an instance of the **SearcherResultsEntry** object.
2. Set the **Filter** property of the **DirectorySearcher** object to the value that you want to search for.
3. Initialize the search by calling the **FindAll** method of the **DirectorySearcher**. The **DirectorySearcher** object will return a collection of all objects in the target directory whose values match those specified in its **Filter** property.

   The following example searches a directory for the user name "John" and then iterates through the returned collection, writing each object's path to a console. Note that this example will not search subdirectories.

```
' Visual Basic
Dim entry As New DirectoryServices.DirectoryEntry("LDAP://Path")
Dim mySearcher As New System.DirectoryServices.DirectorySearcher(entry)
Dim result As System.DirectoryServices.SearchResult
mySearcher.Filter = ("(anr= John)")
For Each result In mySearcher.FindAll()
   Console.WriteLine(result.GetDirectoryEntry().Path)
Next

// C#
System.DirectoryServices.DirectoryEntry entry =
   new System.DirectoryServices.DirectoryEntry("LDAP://Path");
System.DirectoryServices.DirectorySearcher mySearcher = new
   System.DirectoryServices.DirectorySearcher(entry);
mySearcher.Filter = ("(anr= John)");
foreach(System.DirectoryServices.SearchResult result in
   mySearcher.FindAll())
{
   Console.WriteLine( result.GetDirectoryEntry().Path );
}
```

Introduction to Active Directory Objects | Walkthrough: Adding Active Directory Objects | Removing Active Directory Nodes | Modifying Object Properties in an Active Directory Hierarchy

Walkthrough: Adding Active Directory Objects

The procedures in this topic demonstrate the process of using the **DirectoryEntry** component to list the users, groups, and services on your local computer. The **DirectoryEntry** component uses Active Directory technology to do this work. Each entry created by the component contains a list of its properties.

To create the user interface

1. On the **File** menu, point to **New**, and then click **Project**.
2. In the **New Project** dialog box, choose Visual Basic or Visual C# in the left pane, then choose the **Windows Application** template. Name the project **ActiveDirectory**.
3. From the **Windows Forms** tab of the Toolbox, drag a **TreeView** control onto Form1.
4. Set the **Name** property of the **TreeView** control to **viewPC**.

   The **TreeView** control will be modified later in the walkthrough to contain three top-level nodes, one each for users, groups, and services. Each second-level node will represent one user, group, or service registered on your computer. Each user, group, and service will have two child nodes, one for its Active Directory path and one for its properties.

To configure a DirectoryEntry component

1. In Solution Explorer, right-click your project and select **Add Reference** from the shortcut menu.
2. Add a reference to **System.DirectoryServices.dll**.
3. From the **Components** tab of the Toolbox, drag a **DirectoryEntry** component instance to the designer.
4. Set the **Name** property of the **DirectoryEntry** component to **entryPC**.
5. Set the **Path** property of the **DirectoryEntry** component to **WinNT:*//Domain/YourComputerName***. Use your domain and computer name to direct the **DirectoryEntry** component to examine your local computer using the WinNT service provider for Active Directory.

   Note If you do not know your domain or computer name, contact your system administrator.

   Tip If you have the incorrect domain or computer name, the application will throw an exception at run time. You can enter **WinNT:*//YourComputerName*** for the path, and the service provider will attempt to locate the computer.

To add the top-level nodes to the TreeView control

1. In the designer, double-click **Form1** to create the **Form_Load** event handler in the Code Editor.
2. Modify the **Form_Load** method by adding code to create the three top-level nodes for users, groups, and services. When the application runs, the **Children** property of the component named **entryPC** contains all the entries found in **Path** (your computer). Each child is also a **DirectoryEntry** object. Because you are using the WinNT provider on a computer path, the **SchemaClassName** property of the child **DirectoryEntry** object will be one of "User", "Group", or "Service". A select or switch statement can be used to determine the entry type and add a node to the correct group.

   You will write the **AddPathAndProperties** method in the next step.

```
' Visual Basic
Private Sub Form1_Load(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles MyBase.Load
   Dim users As New TreeNode("Users")
   Dim groups As New TreeNode("Groups")
   Dim services As New TreeNode("Services")
   viewPC.Nodes.AddRange(New TreeNode() {users, groups, services})

   Dim child As System.DirectoryServices.DirectoryEntry
   For Each child In entryPC.Children
      Dim newNode As New TreeNode(child.Name)
      Select Case child.SchemaClassName
         Case "User"
            users.Nodes.Add(newNode)
         Case "Group"
```

```
            groups.Nodes.Add(newNode)
         Case "Service"
            services.Nodes.Add(newNode)
      End Select
      AddPathAndProperties(newNode, child)
   Next
End Sub

// C#
private void Form1_Load(object sender, System.EventArgs e)
{
   TreeNode users = new TreeNode("Users");
   TreeNode groups = new TreeNode("Groups");
   TreeNode services = new TreeNode("Services");
   viewPC.Nodes.AddRange(new TreeNode[] { users, groups, services });

   foreach(System.DirectoryServices.DirectoryEntry child
      in entryPC.Children)
   {
      TreeNode newNode = new TreeNode(child.Name);
      switch (child.SchemaClassName)
      {
         case "User" :
            users.Nodes.Add(newNode);
            break;
         case "Group" :
            groups.Nodes.Add(newNode);
            break;
         case "Service" :
            services.Nodes.Add(newNode);
            break;
      }
      AddPathAndProperties(newNode, child);
   }
}
```

3. Add the following code to the **Form1** class to create the `AddPathAndProperties` method. The `node` parameter represents the **TreeNode** object associated with that entry. The `entry` parameter represents one entry in the directory: a user, a group, or a service.

   The **DirectoryEntry** component has a **Properties** property that contains a string-indexed collection of properties. The contents of this collection depend on the schema of the **DirectoryEntry** component. The **Properties** collection has a **PropertyNames** property, which is a collection of all the names of the properties. By stepping through this collection, you can retrieve each property. Each property also has a collection of associated values. In this method, you only retrieve the first value for each property.

```
' Visual Basic
Private Sub AddPathAndProperties(ByVal node As TreeNode, _
ByVal entry As System.DirectoryServices.DirectoryEntry)
   node.Nodes.Add(New TreeNode("Path: " & entry.Path))
   Dim propertyNode As New TreeNode("Properties")
   node.Nodes.Add(propertyNode)

   Dim propertyName As String
   Dim oneNode As String
   For Each propertyName In entry.Properties.PropertyNames
      Try
         oneNode = propertyName & ": " & _
            CType(entry.Properties(propertyName)(0), String)
```

```
        Catch
           oneNode = propertyName & ": " & _
              "No text representation."
        End Try
        propertyNode.Nodes.Add(New TreeNode(oneNode))
     Next
  End Sub

  // C#
  private void AddPathAndProperties(TreeNode node,
     System.DirectoryServices.DirectoryEntry entry)
  {
     node.Nodes.Add(new TreeNode("Path: " + entry.Path));
     TreeNode propertyNode = new TreeNode("Properties");
     node.Nodes.Add(propertyNode);
     foreach (string propertyName in entry.Properties.PropertyNames)
     {
        string oneNode = propertyName + ": " +
           entry.Properties[propertyName][0].ToString();
        propertyNode.Nodes.Add(new TreeNode(oneNode));
     }
  }
```

To run the program

1. Press F5 to run the program.
2. Open the nodes to examine the paths and properties. The users all share the same set of properties, because they all share the same schema. The same is true of the group and service nodes.

Next Steps

This walkthrough used the WinNT service provider for Active Directory. Other services are available, including the Lightweight Directory Access Protocol (LDAP), the Novell NetWare Directory Service (NDS), and the Novell Netware 3.x service (NWCOMPAT). Each provider provides a different set of objects to allow you to examine and manipulate directories.

The **DirectorySearcher** component can be used to search for entries from a root path. The **DirectorySearcher** works with the LDAP provider.

Creating Installation Components

Installation components allow you to set up custom actions that will occur when your application is deployed. You do this if your application requires additional system resources — such as databases, configuration files, Windows event logs, message queues, or services — to be set up and configured in order to work correctly.

Introduction to Installation Components

In Microsoft Visual Studio 6.0, application setup typically involved copying all of the run-time and support files associated with an application from the development computer to the target computer. In Visual Studio .NET, an application consists not only of the traditional program files but also of associated resources, such as message queues, event logs, performance counters, databases, and configuration files, that must be created on the target computer, as well. You can configure your application to create these resources when your application is installed and to remove them if your application is uninstalled, using what are called *installation components*.

For example, suppose you are deploying an application that writes to a custom performance counter. The counter must be installed when the application is deployed. Using an installation component, you can set up the application so that it automatically creates and configures the necessary performance counter on a remote computer when the application is installed.

There are two types of installation components: *installer classes* that can be added to your project, and *pre-defined installation components* that are associated with components.

Installer classes can be added to any application to perform actions during installation (for example, creating a database on a target computer). In a deployment project, the compiled installer classes from your project are added as custom actions that are run at the end of installation. Deployment projects also have the ability to capture user input during installation and pass it to the installer class using the **CustomActionData** property — for example, you might want to let the user choose a location for a database. For more information on consuming installation components in deployment projects, see Walkthrough: Using a Custom Action to Create a Database During Installation.

Predefined installation components are associated on a one-to-one basis with the components that need them. For example, if you have an instance of the **MessageQueue** component in your project and it requires your deployed application to have a queue installed and configured, you create an installation component to handle the task. If you then add an instance of the **EventLog** component to your project and want to configure the event log in use, you must add a second installation component to perform that processing.

There are five predefined installation components that you can use in your projects:

- The **EventLog** installer (based on the **System.Diagnostics.EventLogInstaller** class) allows you to install and configure a custom event log that your application needs in order to run. For more information, see Introduction to the EventLog Component.
- The **MessageQueue** installer (based on the **System.Messaging.MessageQueueInstaller** class) allows you to install and configure a queue that your application needs in order to run. For more information, see Creating Messaging Components.
- The **PerformanceCounter** installer (based on the **System.Diagnostics.PerformanceCounterInstaller** class) allows you to install and configure a custom performance counter that your application needs in order to run. For more information, see Monitoring Performance Thresholds.
- The **Service** and **ServiceProcess** installers (based on the **System.ServiceProcess.ServiceInstaller** and **System.ServiceProcess.ServiceProcessInstaller** classes) are used together to allow you to install service applications. For more information, see Monitoring Windows Services.

All of the installation components in a project are stored within classes marked with the **RunInstallerAttribute=True**. By default, a class named **ProjectInstaller** that contains this attribute is added to your project when you add a predefined installation component; installer classes added via the **Add New Item** dialog box also contain this attribute and are named **Installer1** by default. For more information on what happens during the installation process, see Installation Process.

Framework Component Deployment and the Design Process | Installation Process | Introduction to the EventLog Component | Introduction to Messaging | Monitoring Performance Thresholds | Monitoring Windows Services | Walkthrough: Installing an Event Log Component

Framework Component Deployment and the Design Process

When you create framework components, such as **MessageQueue** and **EventLog** components, the standard development practice assumes that you will first create the necessary system resources on a test computer, using Server Explorer, and then create your components and link them to that test resource.

For example, suppose you are building an order entry system that uses a queue called OrdersReceived to process user data. As your first step, you would create the OrdersReceived test queue and set all of the necessary properties to configure it in a way appropriate for your application. You might set properties to determine the maximum queue size and turn on journal recording for that queue.

After creating the OrdersReceived queue on a test computer, you would create your project and add an instance of the **MessageQueue** component to it, linking it to the queue. You would then write your code, compile, and test the project without having to deploy it to the final server on which it will reside.

When you are ready to deploy your project, you move it from the test server to its final location on a production server, where the necessary resources that the application used on your test machine need to be recreated. Rather than manually configuring these resources on the new server, you can use installation components to do this work for you. When you add an installation component to your project, it accesses the existing test resources and copies the properties you set when you configured the resources, so that the same resource can later be recreated on the production server.

For example, in the case of the messaging application described above, the installation component for your queue would access the **MessageQueue** component instance and learn from its properties that it accessed a queue called OrdersReceived, on your test server. The installation component would then access the OrdersReceived queue and copy its configuration properties, including the **Path** and **Label**, the journal settings you made, and the maximum queue size. These values are stored in the code for the installation component. When you compile and deploy your project, the necessary resource is created on that computer.

You do not have to follow this design process, but it provides an efficient way to work with your test and production resources. If you do not create and configure a test resource from which property values can be copied to the installation component, you can access the installation component in the **ProjectInstaller** class (or any class with the **RunInstallerAttribute** value set to **true**) and manually set the necessary values to create and install the resource in the state you desire.

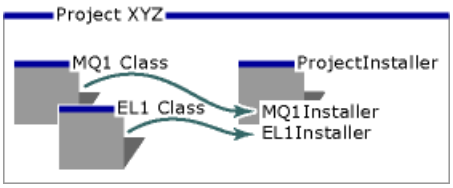
Introduction to Installation Components | Installation Process

Installation Process

When you create installation components for your Framework Services components, a default class called **ProjectInstaller** is created in your project. This file contains all of the installation components you create for that project. The following figure shows this process.

Installation Components and Project

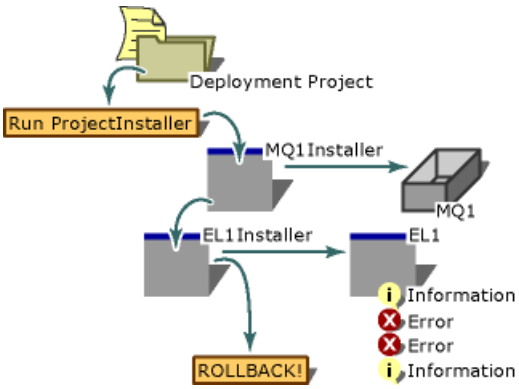


After you create an installation component and its associated **ProjectInstaller** class for your project, you compile the project into a DLL or EXE. You then can do one of two things:

- You can use the **installutil.exe** tool to install that DLL on your local computer.
- You can create a deployment package for your application and add your project's DLL to it as a custom action. When deployment occurs, the deployment project recognizes that it needs to run the **ProjectInstaller** class, and it launches the installation process for your component resources.

Resource installation is transactional. That is, the installation processes through each installer in your **ProjectInstaller** class (or any class with the **RunInstallerAttribute** value set to **true**) and makes sure that no errors occur before committing the installation as final. If any errors occur along the way, all of the resources that have previously been installed are uninstalled in a rollback transaction. Rollback is performed in the reverse order of install. The following figure shows this process.

Installation Process



In this picture, the **ProjectInstaller** class is installing two component resources — a message queue and an event log. The message queue installation succeeds without error, so processing is passed on to the event log installation. An error is encountered in this log, so a rollback begins. During the rollback, the message queue is uninstalled and the system is returned to its original state. For more information on how the **Rollback** method works, see State Storage in the Installation Process.

For a list of the overall steps in creating and testing an installation component, see Creating Installation Components - High-Level Process.

See Also

Introduction to Installation Components | State Storage in the Installation Process | Creating Installation Components - High-Level Process

State Storage in the Installation Process

During installation of components, the **ProjectInstaller** class (or any class with the **RunInstallerAttribute** value set to **true**) writes a file with the extension .**InstallState** to the deployment computer. This file is used to store information about the original state of the system before your resources were installed, and the changes that were made during installation. This file is used in each of the installation component's methods:

- The **Install** method accesses a blank copy of this file in the **stateSaver** parameter, and uses it to write information about all of the successful installations it performs.
- The **Commit** method receives information from the file in the **savedState** parameter. You can work with the contents of this file using the **IDictionary** object if you want to.
- The **Rollback** method receives information from the file in the **savedState** parameter, and uses it to undo previous transactions if an error occurs in the **Install** method. After rollback completes, the state file is deleted.
- The **Uninstall** method receives information from the file in the **savedState** parameter and uses the file to return the system to its original state.

The **InstallState** file is saved on the deployment computer to the same directory in which your project's DLL is installed. You should not modify this file directly, but you can use the **IDictionary** object to work with its contents.

Introduction to Installation Components

Creating Installation Components - High-Level Process

These are the overall steps in creating and testing an installation component for one of your resource-dependent components. See the procedures referenced in this section for more details on each step.

To create an installation component

1. For each component in your application that needs a system resource installed during deployment, add an installation component to your application. For details, see Adding Installation Components to Your Projects.
2. In the **ProjectInstaller** class for your project, customize any properties or methods for which you want to override the defaults. For details, see Configuring Installation Components or Overriding Default Methods on Installation Components.

   > **Note** If you are working in the Microsoft .NET Framework SDK, you must instantiate the component installers in the constructor for the **ProjectInstaller** class and add them to the list of components to install.

3. Save and compile your application project.
4. Create the deployment project for your project, and add your project's DLL to the Custom Action Editor. For details, see Custom Actions Management in Deployment.
5. Save and compile your deployment project.
6. Deploy the project to the destination computer, and verify that your resource was created correctly. For details, see Deploying Applications and Components.

   > **Note** You can also use the Microsoft Visual Studio .NET tool **installutil.exe** to deploy the installation of the DLL you created in step 3, rather than creating and testing the deployment package.

Adding Installation Components to Your Projects | Configuring Installation Components | Overriding Default Methods on Installation Components

Adding Installation Components to Your Projects

Installation components are used to perform actions during the installation of an application (for example, creating and configuring resources such as message queues or databases). There are two types of installation components: installer classes that can be added to any project, and predefined installation components that are associated with specific components. The procedure for adding installation components differs for each type.

To add an installer class to your project

1. In Solution Explorer, select the project where you want to add the class. On the **Project** menu, choose **Add New Item**.
2. In the **Add New Item** dialog box, select **Installer Class**.
3. Override any methods for which you need to perform custom processing. For details, see Overriding Default Methods on Installation Components.

Microsoft Visual Studio .NET ships predefined installation components that can install resources associated with your **MessageQueue** components, **EventLog** components, Windows service applications, and **PerformanceCounter** components. When you work with an instance of one of these components or application types, you can select a hyperlink in the Properties window to automatically add the appropriate installer to your project.

After you add the first installation component to your project, a class named **ProjectInstaller** appears in your project. Each subsequent installation component you place in the project is also added to that class. The **ProjectInstaller** class is automatically registered with the deployment project for your solution.

Visual Studio .NET automatically copies property values that are needed to create your components to the installation component. In some cases, you may have to modify the copied values. For more information, see Configuring Installation Components.

To add a predefined installation component to your project

1. In the designer, click the component for which you want to add an installation component, and then click the **Add Installer** link in the Properties window.

   > **Note** Predefined installation components are only available for **MessageQueue**, **EventLog**, and **PerformanceCounter** components, and for service applications. If you are working with a service application, you select the Component Designer surface rather than any particular component.

   A **ProjectInstaller** class appears in your project and an installation component is added to it.

2. If necessary, access the **ProjectInstaller** class in the Code Editor and modify any of the values that were copied to the installation component. For details, see Configuring Installation Components.
3. Override any methods for which you need to perform custom processing. For details, see Overriding Default Methods on Installation Components.
4. Continue to perform steps 1 through 3 for each installation component your project needs.

See Also

Configuring Installation Components | Overriding Default Methods on Installation Components

Configuring Installation Components

When an installation component is created for a component in your project, Visual Studio .NET copies property values that are necessary for the installer to recreate the chosen resource. For example, for an **EventLog** installer, the system copies the values of the **Log** and **Source** properties and uses these values during installation to create your log in the correct location.

The property values are copied either from the component or from the resource with which the component interacts on your test server. For example, suppose you have an instance of the **MessageQueue** component that interacts with a test queue called OrdersReceived on a server called server1. When you create an installer for this component, it copies the **Path** property's value from the component, and then uses this to locate the resource on the test machine. All of the properties set for that resource on the test machine are also copied to installation code. If there is no physical test resource, the system copies all of its values from the component, and you need to fill in the missing necessary properties manually in the **ProjectInstaller** class.

The following code shows how the default properties for this **MessageQueue** installer might look in the **ProjectInstaller** class:

```
' Visual Basic
Private WithEvents MessageQueueInstaller1 As System.Messaging.MessageQueueInstaller
Private Sub InitializeComponent()
   Me.MessageQueueInstaller1 = New System.Messaging.MessageQueueInstaller
   MessageQueueInstaller1.MaximumJournalSize = 4294967295&
   MessageQueueInstaller1.BasePriority = 0%
   MessageQueueInstaller1.Path = "server1\OrdersReceived"
   Me.Installers.Add(MessageQueueInstaller1)
End Sub

// C#
private System.Messaging.MessageQueueInstaller messageQueueInstaller1;
private void InitializeComponent()
{
   this.messageQueueInstaller1 = new System.Messaging.MessageQueueInstaller();
   messageQueueInstaller1.MaximumJournalSize = 42949672951;
   messageQueueInstaller1.BasePriority = 0;
   messageQueueInstaller1.Path = "server1\\OrdersReceived";
   this.Installers.Add(messageQueueInstaller1);
}
```

You can manually edit the property values if there is a property that you want to set differently on the deployment computer. In addition to changing default property values, you can also override some of the default methods in the installation component if you want to change the processing that occurs during installation. For more information, see Overriding Default Methods on Installation Components.

To change the default values for an installation component

1. After adding an installation component to your solution, open the **ProjectInstaller** class.
2. Locate the installation component you want to modify, and access it in the Code Editor.
3. Locate the **InitializeComponent** procedure. The default property values for your component are located within this procedure.
4. Make any changes you need to make to the property values that will be used to create your component.

See Also

Adding Installation Components to Your Projects | Overriding Default Methods on Installation Components

Overriding Default Methods on Installation Components

By default, every installation component has the following methods:

- **Install** — All of the installation functions the installer must perform are carried out within this method. The **ProjectInstaller** class (or any class with the **RunInstallerAttribute** value set to **true**) calls **Install** on each of the installation components it contains, and then calls either **Commit** (if the installations were all successful) or **Rollback** (if any errors occurred).
- **Commit** — **Commit** is called after the **Install** method has been successfully run on all of the installation components the installer class contains. At this point, all of the installations are committed. Usually, to avoid raising exceptions, no processing is done in the **Commit** method.
- **Rollback** — The **Rollback** method is used to undo all previous installation work if an error occurs anywhere within the installation process. If any of the installation components contained by the installer class raises an error, all of the installations carried out so far are undone.
- **Uninstall** — **Uninstall** is used to remove installation component resources from the system. Unlike installation, uninstall is not transactional. If one uninstall process fails, the system still attempts to uninstall all of the other resources.

Each of these methods contains default processing that will carry out the required work without modification. If desired, however, you can override and modify the processing in each step. For example, for a **Service** installation component, you might want to modify the default processing that occurs in the **Commit** procedure so that the installation process starts the service after it is successfully installed. You might also modify the **Uninstall** procedure so that each service is stopped before it is uninstalled.

To override default methods for an installation component

1. After adding an installation component to your solution, open the installer class.
2. Locate the installation component you want to modify, and access it in the Code Editor.
3. Override the appropriate method and add the functionality you want. For details, see Overriding Properties and Methods.

> **Tip** Make sure to retain the original processing necessary to install, commit, rollback, or uninstall your resources when you override methods in the **ProjectInstaller** class. In general, you should add code to the existing functions rather than removing existing functionality.

Adding Installation Components to Your Projects | Configuring Installation Components | Walkthrough: Installing an Event Log Component | Overriding Properties and Methods

Walkthrough: Installing an Event Log Component

The procedures in this topic walk you through the process of setting up an installation component for an instance of the **EventLog** component, including creating the component instance, adding an installer for it, and compiling and running the installer.

To create your EventLog component

1. On the **File** menu, point to **New**, and then click **Project**.
2. In the **New Project** dialog box, choose Visual Basic or Visual C# in the left pane, then choose the **Windows Application** template. Name the project **MyEventLog**.
3. From the **Components** tab of the Toolbox, drag an EventLog component to the form.
4. In the Properties window, set the following values:

   - Set the **Log** property to **Application**.
   - Set the **MachineName** property to the name of the server on which the event log resides. Use a period (**.**) for the local computer.
   - Set the **Source** property to the string of your choice. In this case, you can use the name of your project.

5. Save your files.

   Note For more information on creating **EventLog** component instances and setting their properties, see Logging Application, Server, and Security Events.

To create an installation component for your EventLog component

1. In the designer, click the **EventLog1** component.
2. In the **Description** area at the bottom of the Properties window, click the **Add Installer** link.

   A **ProjectInstaller** class appears in your project, and an installation component is added to it.

You can now install and run your application.

To build your installation

- Save your project and build it.

  Note Because this installer will function correctly without changing the existing methods, you do not need to override the **Install**, **Commit**, **Rollback**, and **Uninstall** methods.

A setup project will install the compiled project files and run the installers needed to run a Windows application.

To create a setup project for your application

1. On the **File** menu, point to **Add Project**, then click **New Project**.
2. In the **Project Types** pane, select the **Setup and Deployment Projects** folder.
3. In the **Templates** pane, select **Setup Project**. Name the project **MyEventLogSetup**.

   A setup project is added to the solution.

Next you will add the output from the Windows Service project to the setup.

To add the project output to the setup

1. In Solution Explorer, right-click **MyEventLogSetup**, point to **Add**, then choose **Project Output**.

   The **Add Project Output Group** dialog box appears.

2. **MyEventLog** is selected in the **Project** box.
3. In the list box, select **Primary Output**, then click **OK**.

   A project item for the primary output of **MyEventLog** is added to the setup project.

Now add a custom action to install the MyNewService.exe file.

To add a custom action to the setup

1. In Solution Explorer, right-click the setup project, point to **View**, then choose **Custom Actions**.

   The **Custom Actions** editor appears.

2. In the **Custom Actions** editor, right-click the **Custom Actions** node and choose **Add Custom Action**.

   The **Select Item in Project** dialog box appears.

3. Double-click the **Application Folder** in the list box to open it, select **Primary Output from MyEventLog (Active)**, and click OK.

   The primary output is added to all four nodes of the custom actions, **Install**, **Commit**, **Rollback**, and **Uninstall**.

4. Build the setup project.
5. To install **MyEventLog.exe**, right-click the setup project in the Solution Explorer and select **Install**.

What's New in the Visual Basic Language

Visual Basic .NET has many new and improved language features — such as inheritance, interfaces, and overloading — that make it a powerful object-oriented programming language. As a Visual Basic developer, you can now create multithreaded, scalable applications using explicit multithreading. Other new language features in Visual Basic .NET include structured exception handling, custom attributes, and common language specification (CLS) compliance.

The CLS is a set of rules that standardizes such things as data types and how objects are exposed and interoperate. Visual Basic .NET adds several features that take advantage of the CLS. Any CLS-compliant language can use the classes, objects, and components you create in Visual Basic .NET. And you, as a Visual Basic user, can access classes, components, and objects from other CLS-compliant programming languages without worrying about language-specific differences such as data types. CLS features used by Visual Basic .NET programs include assemblies, namespaces, and attributes.

Visual Basic .NET supports many new or improved object-oriented language features such as inheritance, overloading, the **Overrides** keyword, interfaces, shared members, and constructors.

Also included are structured exception handling, delegates, and several new data types.

What's New in Visual Basic .NET 2003

Visual Basic .NET 2003 has added functionality that simplifies bit manipulation and loop variable declaration.

Bit Shift Operators

Visual Basic .NET now supports arithmetic left and right shift operations on integral data types (**Byte**, **Short**, **Integer**, and **Long**). Arithmetic shifts are not circular, which means the bits shifted off one end of the result are not reintroduced at the other end. The corresponding assignment operators are provided as well. For details, see Bit Shift Operators and Assignment Operators.

Loop Variable Declaration

Visual Basic .NET now allows you to declare a loop variable as part of a **For** or **For Each** loop. You can include an **As** clause for the variable in the **For** or **For Each** statement, provided no variable of that name has been declared outside the loop. The scope of a loop variable declared in this manner is the loop itself. For details, see For...Next Statements and For Each...Next Statements.

What's New in Visual Basic .NET 2002

Visual Basic .NET 2003 also includes the following features, which were introduced in Visual Basic .NET 2002.

Inheritance

Visual Basic .NET supports *inheritance* by allowing you to define classes that serve as the basis for derived classes. Derived classes inherit and can extend the properties and methods of the base class. They can also override inherited methods with new implementations. All classes created with Visual Basic .NET are inheritable by default. Because the forms you design are really classes, you can use inheritance to define new forms based on existing ones. For details, see Inheritance.

Exception Handling

Visual Basic .NET supports *structured exception handling*, using an enhanced version of the **Try...Catch...Finally** syntax supported by other languages such as C++. Structured exception handling combines a modern control structure (similar to **Select Case** or **While**) with exceptions, protected blocks of code, and filters. Structured exception handling makes it easy to create and maintain programs with robust, comprehensive error handlers. For details, see Exception Handling.

Overloading

Overloading is the ability to define properties, methods, or procedures that have the same name but use different data types. Overloaded procedures allow you to provide as many implementations as necessary to handle different kinds of data, while giving the appearance of a single, versatile procedure. For details, see Overloaded Properties and Methods.

Overriding Properties and Methods

The **Overrides** keyword allows derived objects to override characteristics inherited from parent objects. Overridden members have the same arguments as the members inherited from the base class, but different implementations. A member's new implementation can call the original implementation in the parent class by preceding the member name with **MyBase**. For details, see Overriding Properties and Methods.

Constructors and Destructors

Constructors are procedures that control initialization of new instances of a class. Conversely, *destructors* are methods that free system resources when a class leaves scope or is set to **Nothing.** Visual Basic .NET supports constructors and destructors using the **Sub New** and **Sub Finalize** procedures. For details, see Object Lifetime: How Objects are Created and Destroyed.

Data Types

Visual Basic .NET introduces three new data types. The **Char** data type is an unsigned 16-bit quantity used to store Unicode characters. It is equivalent to the .NET Framework **System.Char** data type. The **Short** data type, a signed 16-bit integer, was named **Integer** in earlier versions of Visual Basic. The **Decimal** data type is a 96-bit signed integer scaled by a variable power of 10. In earlier versions of Visual Basic, it was available only within a **Variant**. For details, see Data Types.

Interfaces

Interfaces describe the properties and methods of classes, but unlike classes, do not provide implementations. The **Interface** statement allows you to declare interfaces, while the **Implements** statement lets you write code that puts the items described in the interface into practice. For details, see Interfaces in Visual Basic .NET.

Delegates

Delegates — objects that can call the methods of objects on your behalf — are sometimes described as type-safe, object-oriented function pointers. You can use delegates to let procedures specify an event handler method that runs when an event occurs. You can also use delegates with multithreaded applications. For details, see Delegates and the AddressOf Operator.

Shared Members

Shared members are properties, procedures, and fields that are shared by all instances of a class. Shared data members are useful when multiple objects need to use information that is common to all. Shared class methods can be used without first creating an object from a class. For details, see Shared Members.

References

References allow you to use objects defined in other assemblies. In Visual Basic .NET, references point to assemblies instead of type libraries. For details, see References and the Imports Statement.

Namespaces

Namespaces prevent naming conflicts by organizing classes, interfaces, and methods into hierarchies. For details, see Namespaces.

Assemblies

Assemblies replace and extend the capabilities of type libraries by, describing all the required files for a particular component or application. An assembly can contain one or more namespaces. For details, see Assemblies.

Attributes

Attributes enable you to provide additional information about program elements. For example, you can use an attribute to specify which methods in a class should be exposed when the class is used as a XML Web service. For details, see Attributes.

Multithreading

Visual Basic .NET allows you to write applications that can perform multiple tasks independently. A task that has the potential of holding up other tasks can execute on a separate thread, a process known as *multithreading*. By causing complicated tasks to run on threads that are separate from your user interface, multithreading makes your applications more responsive to user input. For details, see Multithreaded Applications.

Language Changes in Visual Basic

While earlier versions of Visual Basic are targeted for Microsoft Windows client applications, Visual Basic .NET is intended for creating XML Web service applications as well. For this purpose, Visual Basic .NET generates managed code for the common language runtime. This entails changes to the language itself.

The changes in Visual Basic .NET are intended to:

- Simplify the language and make it more consistent.
- Add new features requested by users.
- Make code easy to read and maintain.
- Help programmers avoid introducing coding errors.
- Make applications more robust and easier to debug.

The following topics describe language changes from previous versions in Visual Basic .NET.

In This Section

Programming Element Support Changes Summary

Programming Element Support Changes Summary

Visual Basic .NET changes the manner in which it supports various programming elements, mostly for interoperability with the common language runtime. Many Visual Basic 6.0 elements are renamed, reclassified, or combined with other programming elements for Visual Basic .NET. Several elements are no longer supported, because the common language runtime includes functionality that makes them unnecessary.

For additional information on changes to Visual Basic — including the integrated development environment (IDE), Web functionality, projects, forms, constants, and the **Circle**, **Line**, and **Pset** methods — see Introduction to Visual Basic .NET for Visual Basic Veterans.

The following table lists changed programming elements and their replacements.

Visual Basic 6.0 programming element	Visual Basic .NET equivalent	Namespace, class, or run-time library location
Abs function	Abs Method	System Namespace, Math Class
AscB function	Asc Function	Visual Basic Run-Time Library Members, Strings module
As Any keyword phrase	Not supported in Visual Basic .NET. See Declaration Syntax Changes in Visual Basic	Does not apply
Atn function	Atan Method	System Namespace, Math Class
Calendar property	CurrentCulture Property	System.Globalization Namespace, CultureInfo Class
ChDir statement	ChDir Function	Visual Basic Run-Time Library Members, FileSystem module
ChDrive statement	ChDrive Function	Visual Basic Run-Time Library Members, FileSystem module
Chr$, **ChrB**, functions	Chr Function	Visual Basic Run-Time Library Members, Strings module
Close statement	FileClose Function	Visual Basic Run-Time Library Members, FileSystem module
Cos function	Cos Method	System Namespace, Math Class
Currency data type	Decimal Data Type; see Data Type Changes in Visual Basic	Visual Basic Run-Time Library Members, VariantType Enumeration
CVDate function	DateValue Function	Visual Basic Run-Time Library Members, DateAndTime module
CVError function	Error Statement	Does not apply
Date function, **Date** statement	Now Property, Today Property	Visual Basic Run-Time Library Members, DateAndTime module
Date$ function	DateString Property	Visual Basic Run-Time Library Members, DateAndTime module
Debug.Assert method	Assert, Fail methods	System.Diagnostics Namespace, Debug Class
Debug.Print method	Write, WriteIf, WriteLine, and WriteLineIf methods	System.Diagnostics Namespace, Debug Class
Deftype statements	Not supported in Visual Basic .NET. See Data Type Changes in Visual Basic	Does not apply
DeleteSetting statement	DeleteSetting Function	Visual Basic Run-Time Library Members, Interaction module
DoEvents function	DoEvents Method	System.Windows.Forms Namespace, Application Class
Empty keyword	Nothing	Does not apply
Eqv operator	= Operator; see Boolean Operator Changes in Visual Basic	Does not apply
Exp function	Exp Method	System Namespace, Math Class
FileCopy statement	FileCopy Function	Visual Basic Run-Time Library Members, FileSystem module

Get statement	FileGet Function	Visual Basic Run-Time Library Members, FileSystem module
GoSub statement	Not supported in Visual Basic .NET; use the Return Statement. See Control Statement Changes in Visual Basic	Does not apply
Initialize event	Not supported in Visual Basic .NET; use **Sub New**. See Class and Interface Changes in Visual Basic and Using Constructors and Destructors	Does not apply
Imp operator	Not supported in Visual Basic .NET. See Not and Or operators, and Boolean Operator Changes in Visual Basic	Does not apply
Input #, **Input$** statements, **Input$**, **InputB**, **InputB$** functions	Input Function	Visual Basic Run-Time Library Members, FileSystem module

Language Changes in Visual Basic
Provides an overview of new and changed features in Visual Basic .NET.

Array Bound Changes in Visual Basic

Visual Basic .NET updates the declaration of array bounds to provide interoperability with arrays in other programming languages.

Visual Basic 6.0

In Visual Basic 6.0, the default lower bound of every dimension of an array is 0. You can change this to 1 with the **Option Base** statement. You can also override the default lower bound in individual array declarations.

If you leave the default at 0, the number of elements in the array is equal to the upper bound plus one. The following declaration reserves 21 elements for the array `Weight`:

```
Dim Weight(20) As Single
```

Visual Basic .NET

In Visual Basic .NET, the lower bound of every array dimension is 0, and you cannot declare it to be otherwise. The **Option Base** statement is not supported.

The number you specify for each dimension in the declaration is the upper bound, and the initial element count is equal to the upper bound plus one. The declaration in the preceding example reserves 21 elements for `Weight`, with subscripts 0 through 20.

You can also specify a *zero-length array*, which does not contain any elements, by declaring one of its upper bounds to be –1.

Array Size Declaration Changes in Visual Basic

Visual Basic .NET updates array size declaration for interoperability with the common language runtime.

Visual Basic 6.0

In Visual Basic 6.0, you can specify the size of an array in its declaration, as in the following example:

```
Dim Month(0 To 11) As Integer
```

This causes the array to have a fixed size, which you cannot change with the **ReDim** statement.

Visual Basic .NET

In Visual Basic .NET, an array cannot have a fixed size. The preceding example can be rewritten as either of the following declarations:

```
Dim Month(11) As Integer   ' Reserves 12 elements -- (0) through (11).
Dim Month() As Integer = New Integer(11) {}
```

These declarations are equivalent. Each specifies an initial size, which you can change during execution with the **ReDim** statement. To initialize the elements, you can use the following syntax:

```
Dim Month() As Integer = {1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12}
```

If you specify –1 for one of the dimensions, the array does not contain any elements. A **ReDim** statement can change an array back and forth between empty and nonempty.

Number of Dimensions

Although an array's size can change in Visual Basic .NET, the number of dimensions must be fixed. The following example declares a three-dimensional array:

```
Dim Point( , , ) As Double
```

The **ReDim** statement can set or change the size of each dimension, but the array always remains three-dimensional.

See Also

Arrays | Dim Statement | New | ReDim Statement | Programming Element Support Changes Summary

ReDim Statement Changes in Visual Basic

Visual Basic .NET updates declaration with the **ReDim** statement for simplification and improved readability.

Visual Basic 6.0

In Visual Basic 6.0, you can use the **ReDim** statement to serve as the initial declaration of a dynamic array. The array does not have to be declared anywhere else.

Visual Basic 6.0 also allows you to change the rank of an array with **ReDim**, as in the following example:

```
Dim X(10) As Single
ReDim X(10, 10)
```

Visual Basic .NET

In Visual Basic .NET, you cannot use **ReDim** as a declaration. You must declare an array just like any other variable, using **Dim** or an equivalent statement, before it can appear in a **ReDim** statement.

You cannot change the rank of an array in Visual Basic .NET. The code in the preceding example causes an error.

Data Type Changes

The following topics describe changes to data types between Visual Basic 6.0 and Visual Basic .NET.

In This Section

Data Type Changes in Visual Basic
Describes data type declaration, usage, and conversion.
Integer Data Type Changes in Visual Basic
Covers integer data type updates.
Universal Data Type Changes in Visual Basic
Covers universal data type updates.

Related Sections

Programming Element Support Changes Summary
Provides an alphabetical list of programming elements that have changed or are no longer supported in Visual Basic .NET, and includes their replacements.
Language Changes in Visual Basic
Provides an overview of new and changed features in Visual Basic .NET.

Data Type Changes in Visual Basic

Visual Basic .NET updates data types for interoperability with other programming languages and the common language runtime. The changes affect data type declaration, usage, and conversion.

Visual Basic 6.0

In Visual Basic 6.0, you use the **Deftype** statements — **DefBool**, **DefByte**, **DefCur**, **DefDate**, **DefDbl**, **DefDec**, **DefInt**, **DefLng**, **DefObj**, **DefSng**, **DefStr**, and **DefVar** — to set a variable's default type.

You use the **Currency** data type for calculations involving money and for fixed-point calculations.

A **Date** is stored in a **Double** format using eight bytes.

If two **Variant** variables containing integers are multiplied, an overflow condition causes the data type of the result to be changed to **Double**.

You can use the **LSet** and **RSet** statements to copy a variable of one user-defined type to another variable of a different user-defined type.

Visual Basic .NET

The **Deftype** statements are not supported in Visual Basic .NET. Nor is the **Currency** data type. Instead, use the new **Decimal** data type, which can handle more digits on both sides of the decimal point, for all money variables and calculations. **Decimal** is also directly supported by the common language runtime.

In Visual Basic .NET, the **Date** data type uses the common language runtime **DateTime** data type, which is an eight-byte integer value. Because of these different representations, there is no implicit conversion between the **Date** and **Double** data types. To convert between **Double** and the Visual Basic 6.0 representation of **Date**, use the **ToOADate** and **FromOADate** methods of the **DateTime** structure in the **System** namespace.

If multiplication of two **Object** variables containing integers results in an overflow, the result is changed to the 64-bit **Long** data type.

You cannot use **LSet** and **RSet** to assign one data type to another. Doing so entails a type-unsafe operation, particularly with structures, which could result in unverifiable code.

Integer Data Type Changes in Visual Basic

Visual Basic .NET updates the integer data types for interoperability with other programming languages and with the common language runtime.

The following table shows correspondences between integer types in Visual Basic 6.0 and Visual Basic .NET.

Integer Size	Visual Basic 6.0 type and identifier type character	Visual Basic .NET type and identifier type character	Common language runtime type
8 bits, signed	(none)	(none)	**System.SByte**
16 bits, signed	**Integer** (**%**)	**Short** (none)	**System.Int16**
32 bits, signed	**Long** (**&**)	**Integer** (**%**)	**System.Int32**
64 bits, signed	(none)	**Long** (**&**)	**System.Int64**

On 32-bit systems, 32-bit integer operations are faster than either 16-bit or 64-bit integer operations. This means that in Visual Basic .NET, **Integer** is the most efficient and fundamental numeric type. You can improve performance in your applications by changing your **Long** declarations to **Integer** when you migrate to Visual Basic .NET.

> **Note** If you are interfacing with components created on platforms other than Visual Basic .NET, you must take care that your data types correspond to those of the other components. For example, if you use a **Declare** statement to refer to an external procedure created in Visual Basic 6.0, and the procedure defines an **Integer** argument (two bytes in Visual Basic 6.0), you must identify that argument as **Short** in the **Declare** statement, because that is the two-byte integer type in Visual Basic .NET.

Universal Data Type Changes in Visual Basic

Visual Basic .NET updates the universal data type for interoperability with the common language runtime.

Visual Basic 6.0

In Visual Basic 6.0, **Variant** serves as the universal data type. This means that you can store data of any type in a variable of type **Variant**.

Visual Basic .NET

In Visual Basic .NET, **Object** is the universal data type. A variable of type **Object** can hold data of any type. The **Variant** type is not supported, and all its functionality is supplied by **Object**.

Variant is still a reserved word in Visual Basic .NET, even though it has no syntactical use. This helps avoid confusion with its former meanings.

The **VarType** function returns a member of the **VariantType** enumeration that provides the data type classification of an object variable. You can also use classes in the **System** namespace to obtain numeric data type information for an **Object** instance, as shown in the following code:

```
Dim SomeObj As Object
' ... ... ... ...  SomeObj is assigned some value during processing.
' ... ... ... ...  Now we want to find out the data type of SomeObj.
Dim Dtype As Integer      ' To hold numeric data type result.
Dtype = Type.GetTypeCode(SomeObj.GetType())
```

Provides an alphabetical list of programming elements that have changed or are no longer supported in Visual Basic .NET, and includes their replacements.
Language Changes in Visual Basic
Provides an overview of new and changed features in Visual Basic .NET.

Declaration Syntax Changes in Visual Basic

Visual Basic .NET introduces several changes related to the declaration of programming elements.

Multiple Variable Declaration

Visual Basic .NET revises simultaneous declaration of several variables for simplification.

Visual Basic 6.0

In Visual Basic 6.0, you can declare variables of different types in the same statement, but you must specify the data type of each variable or it defaults to **Variant**. The following example shows multiple declarations and their resulting data types:

```
Dim I, J As Integer             ' I is Variant, J is Integer.
Dim L As Integer, M As Integer  ' L is Integer, M is Integer.
Dim N As Integer, X As Double   ' N is Integer, X is Double.
```

Visual Basic .NET

In Visual Basic .NET, you can declare multiple variables of the same data type without having to repeat the type keyword. The declarations equivalent to those in the preceding example are as follows:

```
Dim I                           ' I is Object.
Dim J As Integer                ' J is Integer.
' -- OR --
Dim I As Object, J As Integer   ' I is Object, J is Integer.
Dim L, M As Integer             ' L is Integer, M is Integer.
Dim N As Integer, X As Double   ' N is Integer, X is Double.
```

External Procedure Declaration

Visual Basic 6.0

In Visual Basic 6.0, when you declare a reference to an external procedure with the **Declare** statement, you can specify **As Any** for the data type of any of the arguments and the return type. The **As Any** keywords disable type checking and allow any data type to be passed in or returned.

Visual Basic .NET

Visual Basic .NET does not support the **Any** keyword. In a **Declare** statement, you must specifically declare the data type of every argument and the return if **Option Strict** is **On**. This improves type safety. You can overload your procedure declaration to accommodate various argument data types. You cannot overload only on return types, but you can use the argument type overloads to vary the return type, or you can turn **Option Strict Off**.

Line Label Declaration

Visual Basic 6.0

In Visual Basic 6.0, a line number can directly precede a statement on the same line, without any separating character.

Visual Basic .NET

Visual Basic .NET requires that every line label be followed by a colon (**:**). A statement can optionally follow the colon on the same line, or the line label and colon can stand alone on the line.

See Also

Universal Data Type Changes in Visual Basic | Procedure Calling Sequence Changes in Visual Basic | Declare Statement | Rules of Procedure Overloading | Option Strict Statement | Data Types | Programming Element Support Changes Summary

String Length Declaration Changes in Visual Basic

Visual Basic .NET updates string length declaration for interoperability with the common language runtime.

Visual Basic 6.0

In Visual Basic 6.0, you can specify the length of a string in its declaration. This causes the string to have a fixed length, as in the following example:

```
Dim Name As String * 30
```

Visual Basic .NET

In Visual Basic .NET, you cannot declare a string to have a fixed length unless you use the VBFixedStringAttribute Class attribute in the declaration. The code in the preceding example causes an error.

You declare a string without a length. When your code assigns a value to the string, the length of the value determines the length of the string, as in the following example:

```
Dim Name As String
' ...
Name = "Name is now 30 characters long" ' Length can be changed later.
```

See Also

String Data Type | Dim Statement | Attributes Used in Visual Basic .NET | Programming Element Support Changes Summary

Structure Declaration Changes in Visual Basic

Visual Basic considers structures and user-defined types (UDTs) to be the same type of programming element. Visual Basic .NET updates structure declaration for unification and improved readability.

Visual Basic 6.0

In Visual Basic 6.0, you declare a structure using the **Type ... End Type** construction. The structure and its members all default to public access. Explicit access declaration is optional. The following example shows a valid structure declaration:

```
Type Employee
   EmpNumber As Integer     ' Defaults to Public access.
   EmpOfficePhone As String
   EmpHomePhone As String   ' Cannot be declared Private inside Type.
End Type
```

Visual Basic .NET

In Visual Basic .NET, the **Type** statement is not supported. You must declare structures using the **Structure** statement as part of a **Structure ... End Structure** construction. Every member of a structure must have an access modifier, which can be **Public**, **Friend**, or **Private**. You can also use the **Dim** statement, which defaults to public access. The structure in the preceding example can be declared as follows:

```
Structure Employee
   Public EmpNumber As Integer     ' Must declare access, even if Public.
   Dim EmpOfficePhone As String    ' Still defaults to Public access.
   Private EmpHomePhone As String  ' Can be made Private inside Structure.
End Structure
```

Visual Basic .NET unifies the syntax for structures and classes. Structures support most of the features of classes, including methods.

See Also

Structure Statement | Dim Statement | Public | Private | Programming Element Support Changes Summary

Variable Scope Changes in Visual Basic

Visual Basic .NET updates local variable scope to support block scope and improve structured programming.

Visual Basic 6.0

In Visual Basic 6.0, any variable declared inside a procedure has procedure scope, so it can be accessed anywhere else within the same procedure. If the variable is declared inside a block — that is, a set of statements terminated by an **End**, **Loop**, or **Next** statement — the variable is still accessible outside the block. The following example illustrates procedure scope:

```
For I = 1 To 10
   Dim N As Long
' N has procedure scope although it was declared within a block.
   N = N + Incr(I)
Next
W = Base ^ N
' N is still visible outside the block it is declared in.
```

Visual Basic .NET

In Visual Basic .NET, a variable declared inside a block has block scope, and it is not accessible outside the block. The preceding example can be rewritten as follows:

```
Dim N As Long = 0
' N is declared outside the block and has procedure scope.
For I As Integer = 1 To 10
   N = N + Incr(I)
Next I
W = Base ^ N
' N is visible outside the block but I is not.
```

Because the **For** statement declares `I` as part of the **For** block, `I` has block scope only.

However, a variable's lifetime is still that of the entire procedure. This is true whether the variable has block scope or procedure scope. If you declare a variable inside a block, and if you enter that block several times during the lifetime of the procedure, you should initialize the variable to avoid unexpected values.

Provides an alphabetical list of programming elements that have changed or are no longer supported in Visual Basic .NET, and includes their replacements.
Language Changes in Visual Basic
Provides an overview of new and changed features in Visual Basic .NET.

Format Function Changes in Visual Basic

The Visual Basic .NET **Format** function now follows the common language runtime specification for formatting data. For details on data formatting in the .NET Framework, see Formatting Types.

The following sections detail the changes Visual Basic .NET makes to the date/time, numeric, and string formats.

Date/Time Format

Visual Basic 6.0

In Visual Basic 6.0, to display a short or long date, you use either the "ddddd" or "dddddd" format specifier. The **DayOfWeek** ("w") and **WeekOfYear** ("ww") specifiers display the day considered to be the first day of the week, and the week considered to be the first week of the year. The lowercase "m" character displays the month as a number without a leading zero. The **Quarter** specifier ("q") displays the quarter of the year as a number from 1 – 4.

To display a minute as a number with or without leading zeros, you use either the "Nn" or the "N" format specifier. The characters "Hh" display the hour as a number with leading zeros, and "ttttt" displays the time as a complete time. To display either an uppercase or lowercase "A" or "P" with any hour before or after noon, you use either "AM/PM", "am/pm", "A/P", "a/p", or "AMPM."

Visual Basic .NET

In Visual Basic .NET, "ddddd" and "dddddd" behave the same as "dddd", displaying the full name of the day. They do not display the short date and long date. **DayOfWeek** ("w") and **WeekOfYear** ("ww") are not supported; instead, use the **DatePart** function as follows:

```
Format(Datepart(DateInterval.Weekday, Now))
Format(Datepart(DateInterval.WeekOfYear, Now))
```

"M" and "m" apply to different things, so both are now case sensitive. Use uppercase "M" only for the month in the date portion of a date/time format, and lowercase "m" only for the minutes in the time portion.

The **Quarter** format specifier is not supported; instead, use the **DatePart** function as follows:

```
Format(DatePart(DateInterval.Quarter, Now))
```

To display the minute as a number with or without leading zeros, use "m" or "mm". The "ttttt" format is no longer supported. "H" and "h" apply to different things, so both are now case sensitive. Use uppercase "H" only for a 24-hour clock, and lowercase "h" only for a 12-hour clock. The AM/PM formats are replaced with "t" and "tt."

Numeric Format

Visual Basic 6.0

In Visual Basic 6.0, the **Format** function converts strings to numbers for you.

Negative numbers with an empty negative format string display an empty string.

Trailing decimal points are displayed.

Visual Basic 6.0 supports four format sections – positive, negative, zero, and null.

The exponent for formatting scientific notation supports the "#" placeholder.

The **Short Date/Time** specifier ("c"), displays a date and time in the ddddd ttttt format.

Visual Basic .NET

In Visual Basic .NET, the **Format** function does not convert strings to numbers for you. Thus, the first of the following two lines of code is invalid in Visual Basic .NET, while the second is valid:

```
Format("1.234", "#.#")   ' Displays "#.#".
Format(CSng("1.234"),"#.#")   ' Displays "1.234".
```

Negative numbers with an empty negative format string display a minus sign, as in the following example:

```
Format(-1, ";")   ' Displays "-".
```

Trailing decimal points are not displayed, as in the following examples:

```
Format(123, "###.")   ' Displays "123"
Format(123, "###.#")   ' Displays "123"
```

Visual Basic .NET supports three format sections – positive, negative, and zero. If a non-zero value rounds to zero according to the first or second format section, the resulting zero is formatted according to the third section.

The exponent for formatting scientific notation does not support the "#" placeholder; use the "0" (zero) placeholder instead. Thus, the first of the following two lines of code is invalid in Visual Basic .NET, while the second is valid:

```
Format(123, "#e+#")   ' Displays "12e+3".
Format(123, "#e+0")   ' Displays "1e+2".
```

The short date/time specifier ("c") is now reserved for **Currency** formatting; for date formatting, use the **General Date/Time** ("g") format.

String Format

Visual Basic 6.0

In Visual Basic 6.0, you create expressions for user-defined format strings with the @, &, <, >, and ! specifiers.

Visual Basic .NET

Visual Basic .NET eliminates support for user-defined format strings, so the @, &, <, >, and ! format specifiers have no meaning and are no longer supported.

Date and Time Changes in Visual Basic | Format Function | DatePart Function | Programming Element Support Changes Summary

Date and Time Changes in Visual Basic

Visual Basic .NET updates the **Date**, **Date$**, **Time**, and **Time$** functions, and replaces the **Now** and **Timer** functions with properties.

Visual Basic 6.0

In Visual Basic 6.0, the **Date** and **Time** functions return the system date and time in the four-byte **Date** format. Similarly, the **Date** and **Time** statements use the Visual Basic 6.0 format to set the system date and time.

The **Date$** and **Time$** functions return the system date and time in **String** format.

The **Now** and **Timer** functions specify the current date and time and the number of seconds elapsed since midnight.

Visual Basic .NET

Visual Basic .NET replaces **Date** and **Time** with the **Today** and **TimeOfDay** properties, which use the eight-byte common language runtime (CLR) **DateTime** structure. This corresponds with the **Date** data type in Visual Basic .NET. You can use **Today** and **TimeOfDay** to both set and fetch the system date and time.

Visual Basic .NET replaces the **Date$** and **Time$** functions with the **DateString** and **TimeString** properties. You can use **DateString** and **TimeString** to both set and fetch the system date and time.

The **Now** and **Timer** functions are replaced by read-only properties of the same names. Their calling sequences remain unchanged.

String ($) Function Changes in Visual Basic

Visual Basic .NET eliminates the need for some functions to have both a **String** version and a **Variant** version.

Visual Basic 6.0

In Visual Basic 6.0, some functions have two versions, one that returns a **String** value and one that returns a **Variant** value. These function pairs are differentiated by a dollar sign ($) suffix for the **String** version; for example, **Chr** and **Chr$**.

Visual Basic .NET

Visual Basic .NET replaces each function pair with a single function. The **Variant** versions are discontinued, and you can call the **String** versions either with or without the $ suffix.

Although only **Trim** is defined, Visual Basic .NET accepts **Trim$** because the $ works as an identifier type character for the **String** data type.

Provides an overview of new and changed features in Visual Basic .NET.

Boolean Operator Changes in Visual Basic

Visual Basic .NET removes two Boolean operators and adds two others to improve performance.

Visual Basic 6.0

In Visual Basic 6.0, Boolean operators — **And**, **Or**, **Not**, and **Xor** — always evaluate all the expressions in their operands.

You use the **Eqv** and **Imp** operators to perform logical equivalences and implications on two expressions.

Visual Basic .NET

In Visual Basic .NET, the **And**, **Or**, **Not**, and **Xor** operators still evaluate all expressions contributing to their operands. Visual Basic .NET also introduces two new operators, **AndAlso** and **OrElse**, that can reduce execution time by *short-circuiting* logical evaluations. If the first operand of an **AndAlso** operator evaluates to **False**, the second operand is not evaluated. Similarly, if the first operand of an **OrElse** operator evaluates to **True**, the second operand is not evaluated.

> **Note** You should be careful using short-circuiting operators. If the second operand contains a procedure call, you cannot rely on that procedure being called every time the operator executes.

The **Eqv** and **Imp** operators are not supported. Use the equals (**=**) comparison operator in place of **Eqv** for both logical and bitwise evaluations. You can replace the logical **Imp** operator with an expression using the **Not** and **Or** operators, as shown in the following example:

```
Result = A Imp B         ' True unless A is True and B is False.
Result = (Not A) Or B    ' Same as A Imp B.
```

You can replace a bitwise **Imp** in the same manner, using **Not** and **Or** on numeric operands.

File Handling Changes in Visual Basic

Visual Basic .NET expands file-handling capabilities while providing compatibility with previous versions of Visual Basic file I/O functions.

Visual Basic 6.0

In Visual Basic 6.0, file handling is accomplished using various file I/O functions such as **Open**, **Input**, **Output**, and **Append**. The File System Object provides an object-oriented method of working with files.

Visual Basic .NET

In Visual Basic .NET, file handling is accomplished through the **System.IO** namespace, which duplicates and expands upon the File System Object. In addition, the **System.IO.File** namespace includes functions that provide compatibility with the older Visual Basic file I/O functions.

The **FileStream** class provides access to standard input and output files and error devices.

The following table lists file-related enumerations available in Visual Basic .NET.

Enumeration	Purpose
FileAccess Enumeration	Defines constants for read, write, or read/write access to a file
FileMode Enumeration	Specifies how the operating system opens a file
FileShare Enumeration	Provides constants for controlling the level of access other FileStream members have to the same file
FileAttributes Enumeration	Provides access to stored attributes, such as whether a file is a directory, is encrypted, hidden, or read-only, or is a system file or a temporary file

Programming Element Support Changes Summary
Provides an alphabetical list of programming elements that have changed or are no longer supported in Visual Basic .NET, and includes their replacements.
Language Changes in Visual Basic
Provides an overview of new and changed features in Visual Basic .NET.

Object Creation Changes in Visual Basic

Visual Basic .NET revises object creation for improved readability and to support constructors with arguments.

Visual Basic 6.0

In Visual Basic 6.0, an object variable declared with the keywords **As New** is initialized to **Nothing**, meaning that no object has yet been created. Every time the variable is encountered during execution, it is evaluated before the code executes. If the variable contains **Nothing**, an object of the appropriate class is created prior to execution of the code that uses it.

Visual Basic .NET

In Visual Basic .NET, there is no implicit object creation. If an object variable contains **Nothing** when it is encountered, it is left unchanged and no instance is automatically created.

You can create an object with the same statement that declares the object variable. Each of the following two lines of code creates an object from a class, `EmpObj`, that is already defined in the application. The two lines are treated as equivalent, with the first being taken as shorthand for the second:

```
Dim Emp As New EmpObj           ' Shorthand for next line.
Dim Emp As EmpObj = New EmpObj  ' EmpObj created; Emp points to EmpObj.
```

In both cases, an instance of the `EmpObj` class is created as soon as the **Dim** statement is executed, and `Emp` is initialized to a reference to the new object.

Parameterized Constructors

Some classes have constructors that take arguments. If you are creating an object from such a class, you can include its arguments in the declaration. The following example shows two equivalent declarations that pass arguments to the object's constructor, with the first being taken as shorthand for the second:

```
Dim Q As New Quark(12, 0.0035)          ' Shorthand for next line.
Dim Q As Quark = New Quark(12, 0.0035)  ' Parameterized constructor.
```

Binary Compatibility Changes in Visual Basic

Visual Basic .NET updates the mechanism for preserving compatibility with older versions of a component.

Visual Basic 6.0

In Visual Basic 6.0, the Binary Compatibility option allows you to automatically retain class and interface identifiers from a previous version of a component when you compile a new version. The new version contains both the old identifiers and the new identifiers, and client applications can continue using the old interface to your component without having to be updated.

Visual Basic .NET

In Visual Basic .NET, binary compatibility is accomplished using attributes. This gives you direct control over the information placed in your compiled component, such as class and interface identifiers, virtual table offsets, and any appropriate COM attributes. Because you can explicitly select attributes for preservation, the Binary Compatibility option is not supported.

Class and Interface Changes in Visual Basic

Visual Basic .NET introduces a number of changes that affect the declaration and usage of classes and interfaces.

Implements Statement

Visual Basic 6.0

In Visual Basic 6.0, a class definition implicitly includes a default interface, which defines the public members of the class. This interface can be referenced by another class. In particular, a class can specify another class name in an **Implements** statement.

Visual Basic .NET

In Visual Basic .NET, classes can have methods, and you can define interfaces explicitly. The properties and methods of a class belong exclusively to the class itself. The **Implements** statement can specify only an interface, not another class.

Global Classes

Visual Basic 6.0

When you create a new class in Visual Basic 6.0, the allowable values of the **Instancing** property include **GlobalSingleUse** and **GlobalMultiUse**. These indicate that other components can invoke the properties and methods of the new class as if they were global functions. An instance of the class is implicitly created the first time one of its members is called. This functionality enables a server to expose properties and methods that can be accessed without qualification.

Visual Basic .NET

Visual Basic .NET provides the same functionality by allowing you to expose standard module members from a server. You can add properties and methods of a shared class to the **System** namespace using the **Imports** statement. Visual Basic .NET does not support the **Instancing** property. You can achieve the effect of **GlobalMultiUse** with **Public** class access and the appropriate constructor access.

Option Private Module Statement

Visual Basic 6.0

In Visual Basic 6.0, the **Option Private Module** statement indicates that the entire module is private, and its components are not accessible outside its project.

Visual Basic .NET

Visual Basic .NET does not support the **Option Private Module** statement. This specification is handled by access modifiers in the **Module** statement.

Default Members

Visual Basic 6.0

In Visual Basic 6.0, you can specify that any particular method or data member is the default member of a class.

Visual Basic .NET

In Visual Basic .NET, a default member of a class or structure can only be a property that takes one or more arguments. This enables interoperability with other programming languages.

Initialization and Termination

Visual Basic 6.0

In Visual Basic 6.0, class modules use the **Initialize** and **Terminate** events to perform any necessary actions at the time of creation and destruction. The **Initialize** event is raised when the object is first encountered following a **New** statement, and

Terminate is raised as soon as the last reference to the object is released. However, you can also call these event methods directly at any time during execution.

Visual Basic .NET

Visual Basic .NET uses the constructor/destructor model, and does not support **Class_Initialize** and **Class_Terminate**. A class uses the **Sub** statement to declare its constructor. This enables support of inheritance, which requires parameterized constructors. It also protects the constructor and destructor from being called except at creation and termination.

Indeterminate Lifetime

Object lifetime is determined by the creation and termination of the object instance. The program determines the creation time of the objects it declares, but termination involves a more complex mechanism.

Visual Basic 6.0

In Visual Basic 6.0, every object instance maintains a reference count. When the last reference to an instance is released and the count goes to zero, the object is terminated immediately.

Visual Basic .NET

In Visual Basic .NET, a destructor is not necessarily called as soon as the last reference is released. This is because the common language runtime maintains a reference tree instead of individual reference counts. The garbage collector traces the reference tree in the background. If it finds an object or group of objects that have no reference from any currently executing code, it calls the destructors of all such objects. It is impossible to predict either the order of this destruction or the time it takes the garbage collector to trace the reference tree. Therefore, the lifetime of an object is indeterminate.

Language Changes in Visual Basic
Provides an overview of new and changed features in Visual Basic .NET.

Parameter Passing Mechanism Changes in Visual Basic

Visual Basic .NET introduces several changes affecting the mechanism of passing arguments to procedures.

Default Passing Mechanism

Visual Basic 6.0

In Visual Basic 6.0, if you do not specify **ByVal** or **ByRef** for a procedure argument, the passing mechanism defaults to **ByRef**. This allows the variable passed into the procedure to be modified in the calling program.

Exposing a variable to modification can lead to a pitfall. In the following example, the passing mechanism defaults to **ByRef**, the value of `ElapsedSeconds` gets altered by **MinutesPastHour**, and `ElapsedSeconds` is displayed incorrectly by **MsgBox**:

```
Function MinutesPastHour(Seconds As Integer) As Integer
   Dim Hours As Integer = Seconds \ 3600
   Seconds = Seconds Mod 3600
   MinutesPastHour = Seconds \ 60
End Function
' ...
ElapsedSeconds = CInt(Timer( ))  ' Integer seconds since midnight.
ExtraMinutes = MinutesPastHour(ElapsedSeconds)
MsgBox "Total seconds: " & ElapsedSeconds & _
       "; minutes past hour: " & ExtraMinutes
```

Passing an argument **ByRef** allows a procedure to change it in the calling program, which can lead to unexpected behavior. And if that procedure calls another procedure and passes the same argument **ByRef**, the chances of unintentionally changing the original variable are increased.

Visual Basic .NET

When you declare a procedure in Visual Basic .NET, the passing mechanism defaults to **ByVal** for every argument. This protects arguments against modification. The declaration in the preceding example can be rewritten as follows:

```
Function MinutesPastHour(ByVal Seconds As Integer) As Integer
```

Passing `Seconds` by value prevents the procedure from accessing the variable in the calling program, and helps avoid the pitfall just described.

Although **ByVal** is the default mechanism, specifying it explicitly for every argument removes uncertainty and makes your code easier to read.

ByRef Property Arguments

Visual Basic 6.0

In Visual Basic 6.0, a property passed to a procedure as a **ByRef** argument is copied into the procedure but not copied out. This means that any modification to such a property argument is not reflected back to the original property in the calling program, even though it was passed **ByRef**.

Visual Basic .NET

In Visual Basic .NET, a property argument passed **ByRef** is copied both into and out of the procedure. The following example demonstrates how a property can be changed by a procedure:

```
Sub Reduce(ByRef Height As Single)
' ... ... ... ... ... ... ...  ' Code to modify Height argument.
End Sub
' ...
Dim Sq As Square = New Square  ' Square has property Side of type Single.
Reduce(Sq.Side)                ' Side is changed when Reduce returns.
```

When a procedure modifies a property argument, the value of the original property is not changed immediately in the calling program. Instead, it is copied out when the procedure returns.

ParamArray Arguments

Visual Basic 6.0

In Visual Basic 6.0, a procedure can specify the **ParamArray** keyword on the last of its arguments to accept an array of **Variant** arguments. You cannot declare the passing mechanism of these arguments. They are always passed **ByRef**.

Visual Basic .NET

In Visual Basic .NET, **ParamArray** arguments are always passed **ByVal**. The arguments in the array must all be of the data type of the **ParamArray** argument.

Procedure Calling Sequence Changes in Visual Basic

Visual Basic .NET introduces several changes affecting procedure-calling sequences. These changes improve syntax consistency.

Parentheses in Procedure Calls

Visual Basic 6.0

In Visual Basic 6.0, parentheses are required around the argument list in **Function** calls. In **Sub** calls, they are required if you use the **Call** statement and forbidden if you do not. The following example shows valid calling statements:

```
Y = Sqrt(X)
Call DisplayCell(2, 14, Value)
DisplayCell 2, 14, Value  ' Variation on previous statement.
```

Visual Basic .NET

In Visual Basic .NET, parentheses are always required around a non-empty argument list in any procedure call. In **Sub** calls, the **Call** statement is optional. The preceding example can be rewritten as follows:

```
Y = Sqrt(X)
DisplayCell(2, 14, Value)
```

If you are calling a procedure without supplying any arguments, you can include empty parentheses or leave them out altogether.

Return Statement

Visual Basic 6.0

In Visual Basic 6.0, you use the **Return** statement only to branch back to the code following a **GoSub** statement. Both statements must be in the same procedure.

Visual Basic .NET

In Visual Basic .NET, the **GoSub** statement is not supported, and you can use the **Return** statement to return control to the calling program from a **Function** or **Sub** procedure.

Procedure Declaration Changes in Visual Basic

Visual Basic .NET introduces several changes related to the declaration of procedures.

Optional Arguments

Visual Basic 6.0

In Visual Basic 6.0, you can declare a procedure argument as **Optional** without specifying a default value. If an optional argument is of the **Variant** type, the procedure code can use the **IsMissing** function to determine whether the argument is present.

Visual Basic .NET

In Visual Basic .NET, every optional argument must declare a default value, which is passed to the procedure if the calling program does not supply that argument. The **IsMissing** function is not needed to detect a missing argument, and it is not supported. The following example shows an optional argument declaration:

```
Sub Calculate(Optional ByVal Switch As Boolean = False)
```

Static Local Variables

Visual Basic 6.0

In Visual Basic 6.0, you can declare a procedure with the **Static** modifier. This causes every local variable within the procedure to be static and to retain its value between calls.

Visual Basic .NET

In Visual Basic .NET, the **Static** keyword is not supported in a **Function** or **Sub** statement. You must individually declare each local variable you want to be **Static**.

Default Property Changes in Visual Basic

Visual Basic .NET updates default property support for simplification and improved readability.

Visual Basic 6.0

In Visual Basic 6.0, default properties are supported on objects. On a **Label** control, for example, **Caption** is the default property, and the two assignments in the following example are equivalent:

```
Dim L As Label
L = "Important"
L.Caption = "Important"
```

While default properties enable a certain amount of shorthand in writing Visual Basic code, they have several drawbacks:

- They can make code more difficult to read. In the preceding example, if you are not familiar with the **Label** control, you cannot tell from the first assignment whether the string `"Important"` is being stored directly in the variable `L` or in a default property.
- Given an object that you plan to use in your code, it is not always easy to discover whether it has a default property, and if so, which property that is.
- Default properties make the **Set** statement necessary in the Visual Basic language. The following example shows how **Set** is needed to indicate that an object reference, rather than a default property, is to be assigned:

```
Dim L1 As Label, L2 As Label
L1 = "Saving"  ' Assign a value to L1's Caption property.
L2 = L1        ' Replace L2's Caption property with L1's.
Set L2 = L1    ' Replace L2 with an object reference to L1.
```

Visual Basic .NET

In Visual Basic .NET, default properties are not supported unless they take arguments. Because of this syntax change, the **Let** and **Set** statements are not needed to specify what is to be assigned, and they are not used in assignment statements. The **Text** property replaces the **Caption** property on the **Label** control, and the preceding example can be rewritten as follows:

```
Dim L1, L2 As Label   ' Both become type Label in Visual Basic .NET.
L1.Text = "Saving"    ' Assign Text property.
L2.Text = L1.Text     ' Copy Text property.
L2 = L1               ' Copy object reference.
```

Let is still a reserved word in Visual Basic .NET, even though it has no syntactical use. This helps avoid confusion with its former meanings. Visual Basic .NET uses the **Set** statement for property procedures that set the value of a property.

Parameterized Properties

Default properties that take arguments are not ambiguous, and they are supported in Visual Basic .NET. Default properties appear most commonly on collection classes. In the **System.Windows.Forms** namespace, for example, the **Form** class supports the following hierarchy:

Form object

Controls property (returns a **ControlCollection** object for this form)

ControlCollection object (default property is **Item**)

Item property (returns a **Control** object for one item in the collection)

Control object

The **Form.Controls** property returns a **ControlCollection** object, and the **ControlCollection.Item** property returns a **Control** object. The following example shows both valid and invalid use of default properties in Visual Basic .NET:

```
Dim F As Form   ' Assume F has been created and initialized.
' ...
F.Controls.Item(0).Text = "Stop"   ' Valid -- no default properties used.
F.Controls(0).Text = "Stop"   ' Valid -- Item is parameterized.
' ...
F(0).Text = "Stop"   ' INVALID -- Form does not have a default property.
F.Controls(0) = "Stop"   ' INVALID -- No default property on Control.
```

Default Property Declaration

In Visual Basic .NET, you specify a property as the default property by beginning its declaration with the **Default** keyword. If you overload the property name, you must specify **Default** in every overload declaration. You cannot declare a default property to be **Shared** or **Private**.

See Also

Property Changes in Visual Basic | Control.Text Property | Label Class | Set Statement | System.Windows.Forms Namespace | Form Class | Control.ControlCollection Class | Control Class | Default | Programming Element Support Changes Summary

Property Changes in Visual Basic

Visual Basic .NET updates the declaration of property procedures and arguments for simplification and interoperability with other programming languages.

Visual Basic 6.0

In Visual Basic 6.0, you use the **Property Get**, **Property Let**, and **Property Set** statements to get and set property values.

Passing a variable the **ByRef** property argument allows a procedure to change that variable in the calling code.

Visual Basic .NET

Visual Basic .NET introduces a unified property declaration syntax that includes the procedures for getting and setting the property's value. This guarantees consistency of property attributes such as access level and overloading. The following example shows the declaration of a property that does not take arguments:

```
Private MonthNum As Integer = 1  ' Internal storage for property value.
Property Month( ) As Integer
   Get
      Return MonthNum
   End Get
   Set(ByVal Value As Integer)
      If Value < 1 Or Value > 12 Then
         ' Error processing for invalid value.
      Else
         MonthNum = Value
      End If
   End Set
End Property   ' Month
```

You can use any name you want for the argument to **Set**. If you do not supply an argument, `Value` is automatically generated.

This syntax change makes the **Property Get** and **Property Set** statements unnecessary, and they are not supported. Because Visual Basic .NET does not allow default properties without arguments, **Property Let** and **Property Set** are not needed to distinguish whether an object reference or a default property is to be assigned. Therefore, the **Property Let** statement also is not supported.

Visual Basic .NET does not support **ByRef** property arguments. If a property procedure has a **ByRef** argument and changes the variable underlying that argument, the property can behave in an unexpected manner. Therefore, all declarations of parameterized properties must specify **ByVal** for the arguments.

Control Flow Changes

The following topics describe changes to control flow between Visual Basic 6.0 and Visual Basic .NET.

In This Section

Control Statement Changes in Visual Basic
Covers changes to statements controlling execution flow.
Exception Handling Changes in Visual Basic
Discusses new support for structured exception handling, and continued support for unstructured exception handling.

Related Sections

Programming Element Support Changes Summary
Provides an alphabetical list of programming elements that have changed or are no longer supported in Visual Basic .NET, and includes their replacements.
Language Changes in Visual Basic
Provides an overview of new and changed features in Visual Basic .NET.

Control Statement Changes in Visual Basic

Visual Basic .NET updates several statements controlling the flow of execution.

Visual Basic 6.0

In Visual Basic 6.0, the **GoSub** statement calls a sub-procedure within a procedure. The **On ... GoSub** and **On ... GoTo** constructions, also known as computed **GoSub** and computed **GoTo**, provide compatibility with early versions of BASIC.

The **While ... Wend** construction loops through code while a specified condition is true.

Visual Basic .NET

In Visual Basic .NET, you can call procedures with the **Call** statement, and the **GoSub** statement is not supported. You can perform multiple branching with **Select...Case** statements, and the **On ... GoSub** and **On ... GoTo** constructions are not supported. However, Visual Basic .NET still supports the **On Error** statement.

Visual Basic .NET retains the **While ... Wend** construction, but replaces the **Wend** keyword with the **End** statement. The **Wend** keyword is not supported.

See Also

Procedure Calling Sequence Changes in Visual Basic | Call Statement | Function Statement | Sub Statement | Return Statement | Select...Case Statements | On Error Statement | End Statement | Programming Element Support Changes Summary

Exception Handling Changes in Visual Basic

Visual Basic .NET adds support for structured exception handling, and continues support for unstructured exception handling.

Visual Basic 6.0

In Visual Basic 6.0, you use unstructured exception handling to deal with errors in your code. Placing the **On Error** statement at the beginning of a block of code handles any errors that occur within that block. Unstructured exception handling also employs the **Error** and **Resume** statements.

Visual Basic .NET

In Visual Basic .NET, structured exception handling code detects and responds to errors during execution by combining a control structure with exceptions, protected blocks of code, and filters. Structured exception handling is done through a **Try** statement, which is made up of three kinds of blocks: **Try**, **Catch**, and **Finally**. A **Try** block is a statement block that contains the statement to be executed. A **Catch** block is a statement block that handles an exception. A **Finally** block contains statements to be run when the **Try** statement is exited, regardless of whether an exception has occurred. The **Throw** statement, used in conjunction with a **Catch** block, raises an exception that is represented by an instance of a type derived from the **System.Exception** class.

Program Structure and Code Conventions

This section introduces the typical Visual Basic program structure, provides a simple Visual Basic program, "Hello World", and discusses Visual Basic code conventions. Code conventions are suggestions that focus not on a program's logic but on its physical structure and appearance. Following them makes your code easier to read, understand, and maintain. Code conventions can include, among others:

- Standardized formats for labeling and commenting code.
- Guidelines for spacing, formatting, and indenting code.
- Naming conventions for objects, variables, and procedures.

The following topics present a set of programming guidelines for Visual Basic programs, along with examples of good usage.

In This Section

Structure of a Visual Basic Program
Provides an overview of the elements that make up a Visual Basic program.
The Visual Basic Version of Hello World!
Provides a step-by-step recreation of the classic program "Hello World," redone in Visual Basic .NET.
Visual Basic Naming Conventions
Includes general guidelines for naming procedures, constants, variables, arguments, and objects.
Breaking and Combining Statements in Code
Shows how to divide long statements into multiple lines and combine short statements on one line.
Special Characters in Code
Shows how and where to use non-numeric and non-alphabetic characters.
Comments in Code
Discusses how to add descriptive comments to your code.
Visual Basic Limitations
Discusses the removal of known coding limits within Visual Basic.
Conditional Compilation
Provides links to topics about how to compile particular blocks of code selectively while directing the compiler to ignore others.

Structure of a Visual Basic Program

A Visual Basic program has standard building blocks.

Visual Basic code is stored in project modules. Projects are composed of files, which are compiled into applications. When you start a project and open the code editor, you see some code already in place and in the correct order. Any code that you write should follow this sequence:

1. **Option** statements
2. **Imports** statements
3. The **Main** procedure
4. **Class**, **Module**, and **Namespace**, if applicable, statements

In addition, a program may contain conditional compilation statements. These can be placed anywhere in the module. Many programmers prefer to put them at the end.

If you enter statements in a different order, compilation errors may result.

Option Statements

Option statements establish ground rules for subsequent code, helping prevent syntax and logic errors. The **Option Explicit** statement ensures that all variables are declared and spelled correctly, which cuts back on time spent debugging later. The **Option Strict** statement helps prevent logic errors and data loss that can occur when you work between variables of different types. The **Option Compare** statement specifies the way strings are compared to each other, either by their **Binary** or **Text** arrangement.

Imports Statements

Imports statements allow you to name classes and other types defined within the imported namespace without having to qualify them.

Main Procedure

The **Main** procedure is the "starting point" for your application — the first procedure that is accessed when you run your code. **Main** is where you would put the code that needs to be accessed first. In **Main**, you can determine which form is loaded first when the program is started, find out if a copy of your application is already running on the system, establish a set of variables for your application, or open a database that the application requires. There are four varieties of **Main**:

- `Sub Main()`
- `Sub Main(ByVal CmdArgs() As String)`
- `Function Main() As Integer`
- `Function Main(ByVal CmdArgs() As String) As Integer`

The most common variety of this procedure is **Sub Main( )**. For more information, see The Visual Basic Version of Hello World!.

Class, Module, and Namespace Statements

Classes and modules make up most of the code in your source file. They contain most of the code you write — mainly **Sub**, **Function**, **Method** and **Event** statements — along with variable declarations and other code needed to make your application run.

Conditional Compilation Statements

Conditional compilation statements can appear anywhere within the module. They are set to execute if certain conditions are met during run time. You can also use them for debugging your application, since conditional code runs in debugging mode only.

See Also

Visual Basic Naming Conventions | Visual Basic Limitations | Option Compare Statement | Option Explicit Statement | Option Strict Statement | Imports Statement | Class Statement | Module Statement | Conditional Compilation Overview | Anatomy of the Visual Basic Code Behind Windows Forms | Sub Statement | The Visual Basic Version of Hello World!

The Visual Basic Version of Hello World!

The following console program is the Visual Basic version of the traditional "Hello World!" program, which displays the string `Hello World!`.

```
' A "Hello World!" program in Visual Basic.
Module Hello
   Sub Main()
      MsgBox("Hello World!")   ' Display message on computer screen.
   End Sub
End Module
```

The important points of this program are the following:

- Comments
- The **Main** procedure
- Input and output
- Compilation and execution

Comments

The first line of the example contains a comment:

```
' A "Hello World!" program in Visual Basic.
```

The single quote (') means that the rest of the line is a comment, and will be ignored by the compiler. You can make an entire line a comment, or you can append a comment to the end of another statement, as follows:

```
      MsgBox("Hello World!")   ' Display message on computer screen.
```

The Main Procedure

Every Visual Basic program must contain a procedure called `Main`. This procedure serves as the starting point and overall control for your application. It is called when your module is loaded.

> **Note** If you declare the `Main` procedure in a class, you must use the **Shared** keyword. In a module, `Main` does not need to be **Shared**.

There are four ways to declare the `Main` procedure, as follows:

- The simplest way is to declare a **Sub** procedure that does not take arguments or return a value, as in the earlier console program example:

  ```
  Sub Main()
  ```

- `Main` can also return an **Integer** value, which the operating system uses as the exit code for your program. Other programs can test this code by examining the Windows ERRORLEVEL value. To return an exit code, you must declare `Main` as a **Function** procedure instead of a **Sub** procedure, as follows:

  ```
  Function Main() As Integer
     MsgBox("Hello World!")   ' Display message on computer screen.
     Return 0   ' Zero usually means successful completion.
  End Function
  ```

- `Main` can also take a **String** array as an argument. Each string in the array contains one of the command-line arguments used to invoke your program. You can take different actions depending on their values. To obtain the command-line arguments, you declare `Main` as follows:

  ```
  Function Main(ByVal CmdArgs() As String) As Integer
  ```

```
    Dim ArgNum As Integer   ' Index of individual command-line argument.
    If CmdArgs.Length > 0 Then   ' See if there are any arguments.
       For ArgNum = 0 To UBound(CmdArgs)
          ' Examine CmdArgs(ArgNum) for settings you need to handle.
       Next ArgNum
    End If
    MsgBox("Hello World!")   ' Display message on computer screen.
    Return 0   ' Zero usually means successful completion.
 End Function
```

- You can declare `Main` to examine the command-line arguments but not return an exit code, as follows:

```
Sub Main(ByVal CmdArgs() As String)
```

For more information on the `Main` procedure, see Structure of a Visual Basic Program.

Input and Output

This example uses the standard Visual Basic run-time library, which is available through the **Microsoft.VisualBasic** namespace. You can use all the procedures and properties of **Microsoft.VisualBasic** without having to import it in your program.

The `Main` procedure calls the **MsgBox** function to display a message box containing the string `Hello World!`:

```
        MsgBox("Hello World!")   ' Display message on computer screen.
```

For more information on Windows Forms, see Microsoft.VisualBasic Namespace.

Compilation and Execution

You can compile the "Hello World!" program using either the Visual Studio .NET integrated development environment (IDE) or the command line.

To compile and run the program from the command line

1. Create the source file using any text editor and save it with a file name such as `Hello.vb`.
2. To invoke the compiler, enter the following command:

```
vbc Hello.vb
```

3. If your program does not contain any compilation errors, the compiler creates a `Hello.exe` file.
4. To run the program, enter the following command:

```
Hello
```

You can optionally include the **/main** command-line compiler option in the `vbc` command to specify the namespace and module supplying `Main`.

To compile and run the program from the IDE

1. Create a Visual Basic console application project.
2. Copy the code into the project.
3. Choose the appropriate Build command from the **Build** menu, or F5 to build and run (corresponding to Start in the **Debug** menu).

For more information on the Visual Basic compiler and its options, see Building From the Command Line.

Visual Basic Naming Conventions

When you name an element in your Visual Basic .NET application, the first character of that name must be an alphabetic character, a digit, or an underscore. The following suggestions also apply to naming:

- Begin each separate word in a name with a capital letter, as in `FindLastRecord` and `RedrawMyForm`.
- Begin function and method names with a verb, as in `InitNameArray` or `CloseDialog`.
- Begin class and property names with a noun, as in `EmployeeName` or `CarAccessory`.
- Begin interface names with the prefix "I", followed by a noun or a noun phrase, like `IComponent`, or with an adjective describing the interface's behavior, like `IPersistable`. Do not use the underscore, and use abbreviations sparingly, because abbreviations can cause confusion.
- Begin event handler names with a noun describing the type of event followed by the "`EventHandler`" suffix, as in "`MouseEventHandler`".
- In names of event argument classes, include the "`EventArgs`" suffix.
- If an event has a concept of "before" or "after," use a prefix in present or past tense, as in "`ControlAdd`" or "`ControlAdded`".
- For long or frequently used terms, use abbreviations to keep name lengths reasonable, for example, "HTML", instead of "Hypertext Markup Language". In general, variable names greater than 32 characters are difficult to read on a monitor set to a low resolution. Also, make sure your abbreviations are consistent throughout the entire application. Randomly switching in a project between "HTML" and "Hypertext Markup Language" will lead to confusion.
- Avoid using names in an inner scope that are the same as names in an outer scope. Errors will result if the wrong variable is accessed. If a conflict occurs between a variable and the keyword of the same name, you must identify the keyword by preceding it with the appropriate type library. For example, if you have a variable called `Date`, you can use the intrinsic **Date** function only by calling **System.Date**.

Visual Basic Language and Run-Time Reference

Keywords as Element Names in Code

Any program element — such as a variable, class, or member — can have the same name as a restricted keyword. For example, you can create a variable named `Loop`. However, to refer to your version of it — which has the same name as the restricted **Loop** keyword — you must either qualify it by preceding it with its full namespace, or enclose it in square brackets (**[ ]**), as in the following examples:

```
MyForm.Loop.Visible = True   ' Qualified with the full namespace.
[Loop].Visible = True   ' Square brackets also work.
```

If you do not, Visual Basic assumes use of the intrinsic **Loop** keyword and produces an error, as in the following example:

```
Loop.Visible = True   ' Causes an error.
```

You can use square brackets when referring to forms and controls, and when declaring a variable or defining a procedure with the same name as a restricted keyword. It can be easy to forget to qualify names or include square brackets, and thus introduce errors into your code and make it harder to read. For this reason, it is recommended that you not use restricted keywords as the names of program elements. However, if a future version of Visual Basic defines a new keyword that conflicts with an existing form or control name, you can use this technique when updating your code to work with the new version.

> **Note** Your program also may include element names provided by other referenced assemblies. If these names conflict with restricted keywords, placing square brackets around them forces Visual Basic to accept them.

Conditional Compilation

In *conditional compilation*, particular blocks of code in a program are compiled selectively while others are ignored.

In This Section

Conditional Compilation Overview
Explains what conditional compilation is used for, and discusses the **#Const** and **#If...Then...#Else** directives.

Declaring Conditional Compilation Constants
Shows how to declare conditional compilation constants in the **Property Pages** dialog box, at the command line, or in your code.

Collapsing and Hiding Sections of Code
Explains how to specify a block of code that you can expand or collapse using the Visual Studio .NET outlining feature.

Related Sections

Program Structure and Code Conventions
Provides suggestions for making your code easy to read and maintain.

Compiling to MSIL
Explains how your source code is translated into Microsoft Intermediate language (MSIL) by the compiler.

Compiling MSIL to Native Code
Provides an overview of the .NET framework JIT (just-in-time) compiler that converts MSIL to native (CPU-specific) code.

Conditional Compilation Overview

You can use conditional compilation to select particular sections of code to compile while excluding other sections. For example, you may want to write debugging statements that compare the speed of different approaches to the same programming task, or you may want to localize an application for multiple languages. Conditional compilation statements are designed to run during compile time, not at run time.

You declare a conditional compiler constant in code with the **#Const** directive, and you denote blocks of code to be conditionally compiled with the **#If...Then...#Else** directive. For example, to create French and German language versions of the same application from the same source code, you embed platform-specific code segments in **#If...Then** statements using the predefined constants `FrenchVersion` and `GermanVersion`. The following example demonstrates how:

```
#If FrenchVersion Then
   ' <code specific to the French language version>.
#ElseIf GermanVersion Then
   ' <code specific to the German language version>.
#Else
   ' <code specific to other versions>.
#End If
```

If you set the value of the `FrenchVersion` constant to **True** at compile time, the conditional code for the French version is compiled. If you set the value of the `GermanVersion` constant to **True**, the compiler uses the German version. If neither is set to **True**, the code in the last **Else** block runs.

> **Note** Autocompletion will not function when editing code and using conditional compilation directives if the code is not part of the current branch.

Declaring Conditional Compilation Constants | Collapsing and Hiding Sections of Code | Building from the Command Line | #Const Directive | #If...Then...#Else Directives

Declaring Conditional Compilation Constants

You can set conditional compilation constants in one of three ways:

- In the Property Pages dialog box
- At the command line when using the command-line compiler
- In your code

Conditional compilation constants have a special scope and cannot be accessed from standard code. The scope of a conditional compilation constant is dependant on the way it is set. The following table lists the scope of constants declared using each of the three ways mentioned above.

How Constant is Set	Scope of Constant
Property Pages dialog box	Public to all files in the project
Command line	Public to all files passed to the command-line compile r
#Const statement in code	Private to the file in which it is declared

To set constants in the Property Pages dialog box

- Before creating your executable file, set constants in the Property Pages dialog box by following the steps provided in Setting Visual Basic Project Properties.

To set constants at the command line

- Use the **/d** switch to enter conditional compilation constants, as in the following example:

  ```
  vbc MyProj.vb /d:conFrenchVersion=-1:conANSI=0
  ```

  No space is required between the **/d** switch and the first constant.

Command-line declarations override declarations entered in the Property Pages dialog box, but do not erase them. Arguments set in Property Pages remain in effect for subsequent compilations.

When writing constants in the code itself, there are no strict rules as to their placement, since their scope is the entire module in which they are declared.

To set constants in your code

- Place the constants in the declaration block of the module in which they are used. This helps keep your code organized and easier to read.

Conditional Compilation Overview | Collapsing and Hiding Sections of Code | Building From the Command Line | #If...Then...#Else Directives | #Const Directive

Collapsing and Hiding Sections of Code

The **#Region** directive enables you to collapse and hide sections of code in Visual Basic .NET files. **#Region** lets you specify a block of code that you can expand or collapse when using the Outlining and Hiding Code feature of the Visual Studio .NET Code editor. The ability to hide code selectively makes your files more manageable and easier to read.

#Region directives support code block semantics such as **#If...#End If**. This means they cannot begin in one block and end in another; the start and end must be in the same block. **#Region** directives are not supported within functions.

Syntax

The syntax for **#Region** is as follows:

```
#Region "identifier string"
'code region
#End Region
```

The `identifier string` requires the quotes and acts as the title of the region when it is collapsed. The region is collapsed by default.

To collapse and hide a section of code

- Place the section of code between the **#Region** and **#End Region** statements, as in the following example:

```
#Region "This is the code to be collapsed"
    Private components As System.ComponentModel.Container
    Dim WithEvents Form1 As System.Windows.Forms.Form

   Private Sub InitializeComponent()
      components = New System.ComponentModel.Container
      Me.Text = "Form1"
   End Sub
#End Region
```

Multiple #Region Blocks

The **#Region** block can be used multiple times in a code file; thus, users can define their own blocks of procedures and classes that can, in turn, be collapsed. **#Region** blocks also can be nested within other **#Region** blocks.

> **Note** Hiding code does not prevent it from being compiled, and will not affect the **#If...#End If** statements.

Breaking and Combining Statements in Code

When writing your code, you may at times create lengthy statements that necessitate horizontal scrolling in the Code Editor. While this does not affect the way your code runs, it makes it difficult for you or anyone else to read the code as it appears on the monitor. In such cases, you should consider breaking the single long statement into several lines.

At other times, you may want to consolidate statements on a single line; for instance, when you have several very short statements and want to conserve space. This feature can also be handy when organizing variables or commands within a module.

To break a single statement into multiple lines

- Use the line-continuation sequence, which is a space followed by an underscore (_), at the point at which you want the line to break. In the following example, the statement is broken into four lines with line-continuation sequences terminating all but the last line:

```
Data1.RecordSource = _
  "SELECT * FROM Titles, Publishers" _
& "WHERE Publishers.PubId = Titles.PubID" _
& "AND Publishers.State = 'CA'"
```

Using this sequence makes your code easier to read, both online and when printed.

> **Note** The line-continuation sequence is necessarily the last thing on a line. You cannot follow it with anything else on the same line.

Some limitations exist as to where the line-continuation sequence can be used, such as in the middle of an argument name. You can break an argument list with the line-continuation sequence, but the individual names of the arguments must remain intact.

> **Note** You cannot continue a comment by using a line-continuation sequence. Once a comment begins, the compiler does not examine the characters for special meaning. For a multiple-line comment, repeat the comment symbol (') on each line.

While placing each statement on a separate line is the recommended method, Visual Basic also allows you to place multiple statements on the same line.

To place multiple statements on the same line

- Separate the statements with a colon (**:**), as in the following example:

```
Text1.Text = "Hello" : Red = 255 : Text1.BackColor = Red
```

See Also

Program Structure and Code Conventions | Statements

Labeling Statements

Statement blocks are made up of lines of code delimited by colons. Lines of code preceded by an identifying string or integer are said to be *labeled*. Statement labels are used to mark a line of code to identify it for use with statements such as **On Error Goto**.

> **Note** Labels can be used only on executable statements inside methods.

The following lines of code are labeled with `Jump` and `120`, respectively:

```
Jump: FileOpen(1, "MYFILE", OpenMode.Input)
120: FileClose (1)
```

Labels may be either valid Visual Basic .NET identifiers — such as those that identify programming elements — or integer literals. A label must appear at the beginning of a line of source code and must be followed by a colon, regardless of whether it is followed by a statement on the same line.

The compiler identifies labels by checking whether the beginning of the line matches any already-defined identifier. If it does not, the compiler assumes it is a label.

Labels have their own declaration space and do not interfere with other identifiers. A label's scope is the body of the method. Label declaration takes precedence in any ambiguous situation.

To label a line of code

- Place an identifier, followed by a colon, at the beginning of the line of source code.

Statements | Statements Overview | Program Structure and Code Conventions

Special Characters in Code

At times, you need to use special characters in your code, that is, characters that are not on the standard alphanumeric list. The punctuation and special characters in the Visual Basic .NET character set have various uses, from organizing program text to defining the tasks that the compiler or the compiled program carries out. They do not specify an operation to be performed.

Parentheses

Use parentheses when defining a procedure, such as a **Sub** or **Function**. You must enclose all procedure arguments in parentheses. You also use parentheses for putting variables or arguments into logical groups.

Separators

Separators do what their name suggests: they separate sections of code. In Visual Basic, the separator character is the colon (**:**). Use separators when you want to place multiple statements on a single line instead of separate lines, saving space and improving the readability of your code. The following example shows three statements separated by colons (**:**):

```
a = 5: b = 10: c = 15
```

Concatenation

Use the "**&**" operator for *concatenation*, or linking strings together. Do not confuse it with the **+** operator, which adds together numeric values. Using the "**+**" operator to concatenate may cause incorrect results when operating on two numeric values. The following code provides an example:

```
Var1 = "10.01"
Var2 = 11
Result = Var1 + Var2   ' Result = 21.01
Result = Var1 & Var2   ' Result = 10.0111
```

Member Access Operators

To access a member of a type, you use the dot (**.**) or exclamation point (**!**) operator between the type name and the member name. The type can be an enumeration, structure, interface, or class, and the member can be a field, property, event, or method.

Dot (.) operator

Use the **.** operator as a member access operator for properties, events, fields, and methods, as in the following example:

```
Dim MyForm As New System.Windows.Forms.Form
MyForm.Text = "This is my form"   ' Accesses Text member (property) of Form class (on MyForm
object).
MyForm.CenterToScreen()   ' Accesses CenterToScreen member (method) on MyForm.
```

Exclamation point (!) operator

Use the **!** operator (in a class or interface only) as a dictionary access operator. The class or interface must have a default property that accepts a single **String** argument. The identifier immediately following the **!** operator becomes the string argument to the default property, as in the following example:

```
Public Class HasDefault   ' Exposes a default property.
   Default Public ReadOnly Property Index(ByVal S As String) As Integer
      Get
         Return 1000 + CInt(S)
      End Get
   End Property   ' Index
End Class   ' HasDefault
' ...
Public Class TestHasDefault
   Public Sub CompareAccess()
      Dim HD As HasDefault = New HasDefault()
```

```
        Dim IndexStr As String = "5"
        MsgBox("Traditional access returns " & HD.Index(IndexStr) & vbCrLf & _
               "Default property access returns " & HD(IndexStr) & vbCrLf & _
               "Dictionary access returns " & HD!IndexStr)
    End Sub
End Class   ' TestHasDefault
```

The three output lines of **MsgBox** all display the value 1005. The first line uses the traditional access to property `Index`, the second makes use of the fact that `Index` is the default property of class `HasDefault`, and the third uses dictionary access to the class.

Note that the second operand of the **!** operator must be a valid identifier or keyword. Therefore, the following change to the last line of the **MsgBox** call generates an error because "5" is not an identifier or keyword:

```
               "Dictionary access returns " & HD!"5")
```

> **Note** References to default collections must be explicit. In particular, you cannot use the **!** operator on a late-bound variable.

The **!** character is also used as the **Single** type character.

Program Structure and Code Conventions | Type Characters

Comments in Code

As you read the code examples, you often encounter the comment symbol ('). This symbol tells the Visual Basic compiler to ignore the text following it, or the *comment*. Comments are brief explanatory notes added to code for the benefit of those reading it.

It is good programming practice to begin all procedures and functions with a brief comment describing the functional characteristics of the procedure (what it does), for your own benefit and the benefit of anyone else who examines the code. You should separate the implementation details (how the procedure does it) from comments that describe the functional characteristics. When you include implementation details in the description, remember to update them when you update the function.

Comments can follow a statement on the same line, or occupy an entire line. Both are illustrated in the following code:

```
' This is a comment beginning at the left edge of the screen.
Text1.Text = "Hi!"   ' This is an inline comment.
```

If your comment requires more than one line, use the comment symbol on each line:

```
' The text of this comment is too long to fit on a single line, so we
' break it into two lines. Some comments might need three or more lines.
```

The following chart provides general guidelines for what types of comments should be listed in a particular section of code. These are suggestions; Visual Basic does not enforce "rules" for adding comments. Write what works best, both for you and for anyone else who reads your code:

Section heading	Comment description
Purpose	Describes what the procedure does (not how it does it)
Assumptions	Lists each external variable, control, open file, or other element accessed by the procedure
Effects	Lists each affected external variable, control, or file, and the effect it has (only if it is not obvi ous)
Inputs	Specifies the purpose of the argument
Returns	Explains the values returned by functions

Remember the following points:

- Every important variable declaration should include an inline comment describing the use of the variable being declared.
- Variables, controls, and procedures should be named clearly enough that inline commenting is needed only for complex implementation details.
- Comments cannot follow a line-continuation sequence on the same line.

You can add or remove comment symbols for a block of code by selecting two or more lines of code and choosing the **Comment** and **Uncomment** buttons on the **Edit** toolbar.

> **Note** You can also add comments to your code by preceding the text with the **REM** keyword. However, the **'** symbol and the **Comment**/**Uncomment** buttons are easier to use and require less space and memory.

Visual Basic Limitations

Earlier versions of Visual Basic enforced boundaries in code, such as the length of variable names, the number of variables allowed in modules, and module size. In Visual Basic .NET, these restrictions have been removed, giving you greater freedom in writing and arranging your code. Physical limits still exist, but they are set so high that there is virtually no chance you will exceed them and cause compile errors within your code.

Visual Basic Language Features

The following topics introduce the essential components of Visual Basic .NET, an object-oriented programming language. After creating the interface for your application using forms and controls, you will need to write the code that defines the application's behavior. As with any modern programming language, Visual Basic supports a number of common programming constructs and language elements.

If you've programmed in other languages, much of the material covered in this section may seem familiar. While most of the constructs are similar to other languages, the event-driven nature of Visual Basic introduces some subtle differences.

If you're new to programming, the material in this section serves as an introduction to the basic building blocks for writing code. Once you understand the basics, you can create powerful applications using Visual Basic.

Assemblies

Assemblies form the fundamental unit of deployment, version control, reuse, activation scoping, and security permissions for a .NET-based application. Assemblies take the form of an executable (.exe) file or dynamic link library (.dll) file, and are the building blocks of the .NET Framework. They provide the common language runtime with the information it needs to be aware of type implementations. You can think of an assembly as a collection of types and resources that form a logical unit of functionality and are built to work together.

With Visual Basic .NET, you use the contents of assemblies, and add references to them, in much the same way as you use type libraries with previous versions of Visual Basic. What makes assemblies different from .exe or .dll files in earlier versions of Windows, however, is that they contain all the information you would find in a type library, plus information about everything else necessary to use the application or component.

Assembly Manifest

Within every assembly is an *assembly manifest*. Similar to a table of contents, the assembly manifest contains the following:

- The assembly's identity (its name and version).
- A file table describing all the other files that make up the assembly, including, for example, any other assemblies you created that your .exe or .dll file relies on, or even bitmap or Readme files.
- An *assembly reference list*, which is a list of all external dependencies — .dlls or other files your application needs that may have been created by someone else. Assembly references contain references to both global and private objects. Global objects reside in the global assembly cache, an area available to other applications, somewhat like the System32 directory. The **Microsoft.VisualBasic** namespace is an example of an assembly in the global assembly cache. Private objects must be in a directory at either the same level as or below the directory in which your application is installed.

Because assemblies contain information about content, versioning, and dependencies, the applications you create with Visual Basic .NET do not rely on registry values to function properly. Assemblies reduce DLL conflicts and make your applications more reliable and easier to deploy. In many cases, you can install a .NET-based application simply by copying its files to the target computer.

References

To use an assembly, you must add a reference to it, as described in Adding and Removing References. Next, you use the **Imports** statement to choose the namespace of the items you want to use, as described in References and the Imports Statement. Once an assembly is referenced and imported, all the accessible classes, properties, methods, and other members of its namespaces are available to your application as if their code were part of your source file. A single assembly can contain multiple namespaces, and each namespace can contain a different grouping of items, including other namespaces.

For information on creating assemblies, see Creating and Using Assemblies.

Creating and Using Assemblies

An assembly is one or more .exe or .dll files that make up a Visual Studio .NET-based application. Assemblies are created automatically when you compile Visual Studio .NET source files.

To create an assembly

- Compile your application by choosing **Build** from the **Build** menu, or by building it from the command line using the command line compiler. For details about building assemblies from the command line, see Building From the Command Line.

To add a reference to another assembly

- Choose the **Add Reference** command from the **Project** menu, and select the assembly you want to use. For details, see Adding and Removing References.

To use objects in another assembly

- Specify the fully qualified name for the object, or use an alias that has been defined for the object using an **Imports** statement. For details about fully qualified names, see Namespaces. For details about adding references and using the **Imports** statement, see References and the Imports Statement.

See Also

Assemblies (Visual Basic .NET) | Assemblies | Creating Assemblies | Namespaces | References and the Imports Statement | Adding and Removing References | Imports Statement | Viewing Assembly Contents | Language Changes in Visual Basic | Building From the Command Line

References and the Imports Statement

You can make external objects available to your project by choosing the **Add Reference** command from the **Project** menu. References in Visual Basic .NET can point to assemblies, which are like type libraries but contain more information.

Assemblies include one or more namespaces. When you add a reference to an assembly, you can also add an **Imports** statement to a module that controls the visibility of that assembly's namespaces within the module. The **Imports** statement provides a scoping context that lets you use only the portion of the namespace necessary to supply a unique reference.

The **Imports** statement has the following syntax:

```
Imports [| aliasname =] Namespace
```

Aliasname refers to a short name you can use within code to refer to an imported namespace. *Namespace* is a namespace available through either a project reference, through a definition within the project, or through a previous **Imports** statement.

A module may contain any number of **Imports** statements. They must appear after any **Option** statements, if present, but before any other code.

> **Note** Do not confuse project references with the **Imports** statement or the **Declare** statement. Project references make external objects, such as objects in assemblies, available to Visual Basic .NET projects. The **Imports** statement is used to simplify access to project references, but does not provide access to these objects. The **Declare** statement is used to declare a reference to an external procedure in a dynamic-link library (DLL).

Using Aliases with the Imports Statement

The **Imports** statement makes it easier to access methods of classes by eliminating the need to explicitly type the fully qualified names of references. Aliases let you assign a friendlier name to just one part of a namespace. For example, the carriage return-line feed sequence that causes a single piece of text to be displayed on multiple lines is part of the **ControlChars** class in the **Microsoft.VisualBasic** namespace. To use this constant in a program without an alias, you would need to type the following code:

```
    MsgBox("Some text" & Microsoft.VisualBasic.ControlChars.crlf _
                       & "Some more text")
```

Imports statements must always be the first lines immediately following any **Option** statements in a module. The following code fragment shows how to import and assign an alias to the **Microsoft.VisualBasic.ControlChars** namespace:

```
Imports CtrlChrs=Microsoft.VisualBasic.ControlChars
```

Future references to this namespace can be considerably shorter:

```
    MsgBox("Some text" & CtrlChrs.crlf & "Some more text")
```

If an **Imports** statement does not include an alias name, elements defined within the imported namespace can be used in the module without qualification. If the alias name is specified, it must be used as a qualifier for names contained within that namespace.

Namespaces

Namespaces organize the objects defined in an assembly. Assemblies can contain multiple namespaces, which can in turn contain other namespaces. Namespaces prevent ambiguity and simplify references when using large groups of objects such as class libraries.

For example, Visual Studio .NET defines the **ListBox** class in the **System.Windows.Forms** namespace. The following code fragment shows how to declare a variable using the fully qualified name for this class:

```
Dim LBox As System.Windows.Forms.ListBox
```

Visual Studio .NET namespaces address a problem sometimes known as *namespace pollution*, in which the developer of a class library is hampered by the use of similar names in another library. These conflicts with existing components are sometimes called *name collisions*.

For example, if you create a new class named `ListBox`, you can use it inside your project without qualification. However, if you want to use the Visual Studio .NET **ListBox** class in the same project, you must use a fully qualified reference to make the reference unique. If the reference is not unique, Visual Basic .NET produces an error stating that the name is ambiguous. The following code example demonstrates how to declare these objects:

```
'   Define a new object based on your ListBox class.
Dim LBC as New ListBox
'   Define a new Windows.Forms ListBox control.
Dim MyLB as New System.Windows.Forms.ListBox
```

The following illustration shows two namespace hierarchies, both containing an object named `ListBox`.

By default, every executable file you create with Visual Basic .NET contains a namespace with the same name as your project. For example, if you define an object within a project named `ListBoxProject`, the executable file, ListBoxProject.exe, contains a namespace called `ListBoxProject`.

Multiple assemblies can use the same namespace. Visual Basic .NET treats them as a single set of names. For example, you can define classes for a namespace called `SomeNameSpace` in an assembly named `Assemb1`, and define additional classes for the same namespace from an assembly named `Assemb2`.

Fully Qualified Names

Fully qualified names are object references that are prefixed with the name of the namespace where the object is defined. You can use objects defined in other projects if you create a reference to the class (by choosing **Add Reference** from the **Project** menu) and then use the fully qualified name for the object in your code. The following code fragment shows how to use the fully qualified name for an object from another project's namespace:

```
Dim LBC As New ListBoxProject.Form1.ListBox()
```

Fully qualified names prevent naming conflicts because the compiler can always determine which object is being used. However, the names themselves can get long and cumbersome. To get around this, you can use the **Imports** statement to define an *alias* — an abbreviated name you can use in place of a fully qualified name. For example, the following code example creates aliases for two fully qualified names, and uses these aliases to define two objects:

```
Imports LBControl = System.Windows.Forms.ListBox

Imports MyListBox = ListBoxProject.Form1.ListBox

Dim LBC As LBControl

Dim MyLB As MyListBox
```

If you use the **Imports** statement without an alias, you can use all the names in that namespace without qualification provided they are unique to the project. If your project contains **Imports** statements for namespaces that contain items with the same name, you must fully qualify that name when you use it. Suppose, for example, your project contained the following two **Imports**

statements:

```
Imports MyProj1 ' This namespace contains a class called Class1.
Imports MyProj2 ' This namespace also contains a class called Class1.
```

If you attempt to use `Class1` without fully qualifying it, Visual Basic .NET produces an error stating that the name `Class1` is ambiguous.

Namespace Level Statements

Within a namespace, you can define items such as modules, interfaces, classes, delegates, enumerations, structures, and other namespaces. You cannot define items such as properties, procedures, variables and events at the namespace level, these items must be declared within containers such as modules, structures, or classes.

Attributes

Attributes are keyword-like tags in which you can specify additional information about entities defined in Visual Basic .NET applications. Attributes, which are saved with an assembly's metadata, annotate programming elements such as types, fields, methods, and properties. Other applications, such as the Visual Basic .NET or ASP.NET compilers, can refer to the information in attributes to determine how objects should be used.

The following sections provide more information about attributes and how they are defined, applied, and retrieved.

In This Section

Attributes Overview

Metadata and Self-Describing Components
Provides detailed information about the kinds of metadata used in Visual Studio .NET, including attributes.

Attributes Overview

Attributes are descriptive tags that provide additional information about programming elements such as types, fields, methods, and properties. Other applications, such as the Visual Basic compiler, can refer to the extra information in attributes to determine how these items can be used.

Attributes and Metadata

Attributes are saved with the *metadata* of Visual Basic .NET assemblies. Metadata is information that describes every element managed by the runtime. This includes information required for debugging and garbage collection, as well as security attributes, marshaling data, extended class and member definitions, version binding, and any other information the runtime requires.

With attributes, you specify the metadata in much the same way as you use keywords like **Public** and **Private** to provide information about access levels. However, unlike keywords, most attributes are not language-specific. Using attributes, you can extend the capabilities of the Visual Basic language without requiring changes to the compiler.

Functionality and Capabilities of Attributes

Some key points about attributes include:

- You can apply one or more attributes to entire assemblies, modules, or smaller program elements such as classes and properties.
- Attributes can accept arguments in the same way as methods and properties.
- Attributes fall into two groups: those that are used by the .NET Framework and Visual Basic .NET, and custom attributes that are meaningful only to specific applications.
- While the .NET Framework contains many useful attributes, you can define your own custom attributes if necessary.
- Custom attributes are defined in attribute classes based on the **System.Attribute** class. Attribute classes themselves use **AttributeUsage** to provide additional information about how the attribute can be used.
- The process of retrieving metadata from attributes is called *reflection*. Reflection involves using tools that allow objects to retrieve and examine metadata about their own members.

Attributes Used in Visual Basic .NET

The following table lists some of the more common attributes used in Visual Basic .NET. For information about a specific attribute, type the attribute name in the Index or Search field of the help system.

Attribute	Purpose
COMClassAttribute Class	Indicates to the compiler that the class should be exposed as a COM object. Specific to Visual Basic .NET.
VBFixedStringAttribute Class	Specifies the size of a fixed-length string in a structure for use with file input and output functions. Specific to Visual Basic .NET.
VBFixedArrayAttribute Class	Specifies the size of a fixed array in a structure for use with file input and output functions. Specific to Visual Basic .NET.
WebMethodAttribute Class	Makes a method callable using the **SOAP** protocol. Used in XML Web services.
SerializableAttribute Class	Indicates that a class can be serialized.
MarshalAsAttribute Class	Determines how a parameter should be marshaled between the managed code of Visual Basic .NET and unmanaged code such as a Windows API. Used by the common language runtime.
AttributeUsageAttribute Class	Specifies how an attribute can be used.
DllImportAttribute Class	Indicates that the attributed method is implemented as an export from an unmanaged DLL.

Attributes Specific to Visual Basic .NET

Three attributes are specific to Visual Basic .NET: **COMClassAttribute**, **VBFixedStringAttribute**, and **VBFixedArray**.

COMClassAttribute

Use **COMClassAttribute** to simplify the process of creating COM components from Visual Basic .NET. COM objects are considerably different from .NET assemblies, and without **COMClassAttribute**, you need to follow a number of steps to generate a COM object from Visual Basic .NET. For classes marked with **COMClassAttribute**, the compiler performs many of these steps automatically.

VBFixedStringAttribute

Use **VBFixedStringAttribute** to force Visual Basic .NET to create a fixed-string array. Arrays are of variable length by default, and this attribute is useful when storing strings to files. The following code demonstrates this:

```
Structure Worker
   ' The runtime uses VBFixedString to determine
   ' if the field should be written out as a fixed size.
   <VBFixedString(10)> Public LastName As String
   <VBFixedString(7)> Public Title As String
   <VBFixedString(2)> Public Rank As String
End Structure
```

VBFixedArrayAttribute

Use **VBFixedArrayAttribute** to declare arrays that are fixed in size. Like Visual Basic .NET strings, arrays are of variable length by default. This attribute is useful when serializing or writing data to files.

Common Uses for Attributes

In using the common language runtime and class libraries, you probably will need to use attributes at some point. The following list includes a few of the common uses of attributes in code:

- Marking methods using the **WebMethod** attribute in XML Web services to indicate that the method should be callable over the SOAP protocol. For more information, see WebMethodAttribute Class.
- Describing how to marshal method parameters when interoperating with native code. For more information, see MarshalAsAttribute Class.
- Describing the COM properties for classes, methods, and interfaces.
- Marking components as COM so the Visual Basic compiler will generate the additional code required to create a COM component. For more information, see COMClassAttribute Class.
- Calling unmanaged code using the DllImportAttribute Class.
- Describing your assembly in terms of title, version, description, or trademark.
- Describing which members of a class to serialize for persistence.
- Describing how to map between class members and XML nodes for XML serialization.
- Describing the security requirements for methods.
- Specifying characteristics used to enforce security.
- Controlling optimizations by the just-in-time (JIT) compiler so the code remains easy to debug.

You can use attributes in many additional ways, and you can also create custom attributes.

Application of Attributes

You apply attributes by adding attribute blocks to program elements such as properties, methods, events, classes, and assemblies. An attribute block consists of angle brackets ("< >") enclosing a list of comma-separated attribute declarations. An attribute declaration consists of an optional attribute modifier such as **Module** or **Assembly**, an attribute name, a (possibly overloaded) list of required positional parameters, and a list of optional named arguments. You must place attributes with modifiers in an attributes section at the top of a source file. For example, the following code sets an assembly attribute that defines a title for the assembly, and a module attribute that indicates that the module is compliant with the common language specification (CLS):

```
Option Explicit On
Imports System.Reflection
<Assembly: AssemblyTitleAttribute("Production assembly 4"), _
Module: CLSCompliant(True)>
Namespace MyNameSpace
```

Assembly attributes also can be applied via the AssemblyInfo.vb file, which is added to projects automatically by the Visual Studio .NET user interface. This file contains assembly-level attributes with either default or empty values.

When applied to program elements such as properties, attributes precede the element. For example, the following code applies an attribute to a class definition:

```
<CustomAttr(Update:=True)> Class Class1
```

By convention, all attribute names end with the word "Attribute" to distinguish them from other items in the .NET Framework. However, you do not need to specify the attribute suffix when using attributes. For example, if you had an attribute named `CustomAttrAttribute`, then specifying `<CustomAttr(Update:=True)>` is equivalent to specifying `<CustomAttrAttribute(Update:=True)>`.

Attribute Arguments

Attributes use optional, required, positional, and named arguments in much the same way that objects use these types of arguments. Positional arguments are arguments that are specified in the order they are declared for the constructor of an attribute. For example, the following code calls the **Sub New** constructor of an attribute with two values:

```
<CustomAttr(True, False)>
```

Arguments passed to **Sub New** in attribute classes are often used to initialize the values of fields and properties.

You can use named arguments to directly set the value of properties and fields. You specify a named argument by appending ":=" to the name of the argument, followed by the value being specified. Unlike positional arguments, named arguments can be specified in any order. For example, the following code sets the value **True** for the `Update` field, and **False** for the `Keep` field:

```
<CustomAttr(Update:=True, Keep:=False)>
```

> **Note** Attribute arguments have one important difference from arguments used with standard method calls. You must use positional arguments for arguments that are used with the **Sub New** constructor of attribute classes. Named arguments can only be used to set the values of fields and properties of attribute classes.

Required arguments are those that must always be specified. Optional arguments are those that can be skipped using a comma as a placeholder (when using positional arguments), or simply omitted (when using named arguments).

Attribute Examples

The following procedures provide examples of attribute declarations.

To use the MarshalAs attribute to control how parameters are marshaled

1. Add an **Imports** statement for the **System.Runtime.InteropServices** namespace to the top of your source code:

   ```
   Imports System.Runtime.InteropServices
   ```

2. Prefix parameters with the **MarshalAs** attribute and specify the data type the target requires. For example, the following code marshals two parameters as the data type long pointer to a string (**LPStr**) for a Windows API function:

```
Declare Auto Sub CopyFile Lib "Kernel32.Lib" ( _
   <MarshalAs(UnmanagedType.LPStr)> ByVal existingfile As String, _
   <MarshalAs(UnmanagedType.LPStr)> ByVal newfile As String, _
   ByVal failifexists As Boolean
)
```

The common language runtime uses the **MarshalAs** attribute to determine how a parameter should be marshaled between the managed code of Visual Basic .NET and the unmanaged code in a Windows API call.

To expose a method to remote Web clients

1. From the **File** menu, click **Project**, select the **ASP.NET Web Service** template, and add an **Imports** statement for the **System.Web** namespace:

```
Imports System.Web.Services
```

2. 7Define a method and use the **WebMethod** attribute to make it callable from remote Web clients:

```
<WebMethod()> Public Function HelloWorld() As String
   HelloWorld = "Hello World..."
End Function
```

Making an XML Web service method **Public** is not sufficient to expose it to Web clients. You must explicitly apply the **WebMethod** attribute to a method before it can be called by a remote Web client.

Global Attributes

Most attributes are attached to specific language elements such as classes or methods. However, some attributes are global — they can apply to an entire assembly or module. You specify assembly-level attributes using the following syntax:

```
<Assembly: Attribute1, Assembly: Attribute2..., Assembly: Attributen>
```

You specify module-level attributes using similar syntax:

```
<Module: Attribute1, Module: Attribute2..., Module: Attributen>
```

You place global attributes in source code after any top-level directives, such as **Option Explicit** and **Imports** statements, but before any type or namespace declarations. Global attributes can appear in multiple source files in a project, but they are generally placed in the file AssemblyInfo.vb file created automatically with Visual Basic .NET projects.

Assembly Attributes

Assembly attributes are values that provide information about an assembly. They fall into the following categories:

- Assembly identity attributes
- Informational attributes
- Assembly manifest attributes
- Strong name attributes

Assembly Identity Attributes

Three attributes (with a strong name, if applicable) determine the identity of an assembly: name, version, and culture. These attributes form the full name of the assembly and are required when referencing it in code. You can set an assembly's version and culture using attributes. The name value, however, is set by the compiler or the Assembly Linker (Al.exe) when the assembly is created, based on the file containing the assembly manifest. The **AssemblyFlags** attribute specifies whether multiple copies of the assembly can coexist.

The following table shows the identity attributes.

Attribute	Purpose
AssemblyName Class	Fully describes an assembly's identity
AssemblyVersionAttribute Class	Specifies the version of an assembly
AssemblyCultureAttribute Class	Specifies which culture the assembly supports
AssemblyFlagsAttribute Class	Specifies whether an assembly supports side-by-side execution on the same machine, in the same process, or in the same application domain

The following code applies the version and culture attributes to an assembly:

```
'Set version number for assembly.
<Assembly:AssemblyVersionAttribute("4.3.2.1")>
'Set culture as German.
<Assembly:AssemblyCultureAttribute("de")>
```

Informational Attributes

You can use informational attributes to provide additional company or product information for an assembly. The following table shows the informational attributes defined in the **System.Reflection** namespace.

Attribute	Purpose
AssemblyProductAttribute Class	Defines a product name custom attribute for an assembly manifest
AssemblyTrademarkAttribute Class	Defines a trademark custom attribute for an assembly manifest
AssemblyInformationalVersionAttribute Class	Defines an assembly informational version custom attribute for an assembly manifest

AssemblyCompanyAttribute Class	Defines a company name custom attribute for an assembly manifest
AssemblyCopyrightAttribute Class	Defines a copyright custom attribute for an assembly manifest
AssemblyFileVersionAttribute Class	Instructs the compiler to use a specific version number for the Win32 file version resource

Assembly Manifest Attributes

You can use assembly manifest attributes to provide information in the assembly manifest, including title, description, default alias, and configuration. The following table shows the assembly manifest attributes defined in the **System.Reflection** namespace.

Attribute	Purpose
AssemblyTitleAttribute Class	Defines an assembly title custom attribute for an assembly manifest
AssemblyDescriptionAttribute Class	Defines an assembly description custom attribute for an assembly manifest
AssemblyConfigurationAttribute Class	Defines an assembly configuration custom attribute (such as retail or debug) for an assembly manifest
AssemblyDefaultAliasAttribute Class	Defines a friendly default alias for an assembly manifest

Strong Name Attributes

Strong names are unique identifiers that protect the identity and integrity of an assembly. You can use strong name attributes to set a strong name for an assembly. The following table shows the strong name attributes defined in the **System.Reflection** namespace.

Attribute	Purpose
AssemblyDelaySignAttribute Class	Boolean that indicates whether you want to reserve space in the executable file for the strong name signature, but defer the actual signing until some later stage. For more information, see Delay Signing an Assembly.
AssemblyKeyFileAttribute Class	Indicates the file that contains a key. The location of the KeyFile should be relative to the project output directory, which is %Project Directory%\obj\<configuration>. For example, if your KeyFile is located in the project directory, you would specify the AssemblyKeyFile attribute as [assembly: AssemblyKeyFile("..\\..\\mykey.snk")]
AssemblyKeyNameAttribute Class	Refers to a key that has been installed in the Crypto Service Provider (CSP) on your machine. You must specify a key in order for your file to be signed.

If the KeyFile and the KeyName values are both specified, the following processing occurs:

- If the KeyName can be found in the CSP, that key is used.
- If the KeyName does not exist and the KeyFile does exist, the key in the KeyFile is installed into the CSP and used.
- For more information, see Assembly Security Considerations.

Signing Assemblies

You can sign an assembly in two different, but complementary ways: with a strong name or using the File Signing Tool (Signcode.exe). Signing an assembly with a strong name adds a public key encryption to the file containing the assembly manifest. Strong name signing ensures name uniqueness, prevents name spoofing and provides callers with some identity when a reference is resolved. For more information, see Signing an Assembly with a Strong Name.

To sign an assembly with a strong name

1. Use the Strong Name Tool (Sn.exe) to generate a key file containing a key pair.
2. Add strong name attributes to the AssemblyInfo.vb file created automatically with Visual Basic .NET projects. You can edit this file by double clicking its name in the **Solution Explorer**.

The following example uses delay signing to create a strong-named assembly with a public key file called `myKey.snk`.

```
<Assembly: AssemblyKeyFile("myKey.snk")>
<Assembly: AssemblyDelaySign(True)>
```

> **Note** Assembly-level attributes are ignored if you are not creating an assembly, such as when compiling from the command line using the **/target:module** option.

Custom Attributes

Custom attributes are user-defined attributes that provide additional information about program elements. For example, you might define a custom security attribute that specifies the permissions required by the caller to execute a procedure.

You define custom attributes in attribute classes based on the **System.Attribute** class. Attribute classes themselves use an attribute called **AttributeUsage** to provide information about how the attribute can be used. Specifying **Inherited** = **True** indicates that an attribute can propagate to derived classes. Setting the **AllowMultiple** property to **True** allows you to apply more than one instance of the attribute to a program element. The **AttributeTargets** enumeration lets you define which kinds of program elements your attribute can apply to.

In the following code, the **AttributeUsage** attribute specifies an attribute that can be applied to any type of item, inherited, and applied only once:

```
<AttributeUsage(AttributeTargets.All, Inherited := True, AllowMultiple := False)>
```

You can use the **Or** operator to combine multiple items from the **AttributeTargets** enumeration, as in the following code:

```
<AttributeUsage(AttributeTargets.Class Or AttributeTargets.Method)>
```

Metadata and Self-Describing Components
Provides detailed information about the kinds of metadata used in Visual Studio .NET, including attributes.

Defining Your Own Attributes

Using attribute classes, you can create your own custom attributes, and use them in addition to the .NET Framework attributes to provide additional information about program elements.

To define a custom attribute

1. Declare a class and apply the **AttributeUsage** attribute to it. The name of your class is the name of the new attribute, as shown in the following code:

```
<AttributeUsage(AttributeTargets.All)> Class TestAttribute
```

2. Add an **Inherits System.Attribute** statement as the first line of code in the class:

```
Inherits System.Attribute
```

3. Define **Private** fields to store property values:

```
Private m_SomeValue As String
```

4. If appropriate, create a constructor for the attribute:

```
Public Sub New(ByVal Value As String)
   m_SomeValue = Value
End Sub
```

5. Define methods, fields, and properties for the attribute:

```
Public Sub Attr(ByVal AttrValue As String)
   'Add method code here.
End Sub
Public Property SomeValue() As String  ' A named parameter.
   Get
      Return m_SomeValue
   End Get
   Set(ByVal Value As String)
      m_SomeValue = Value
   End Set
End Property
```

6. End the class with the **End Class** construct:

```
End Class
```

See Also

Application of Attributes | Object Lifetime: How Objects Are Created and Destroyed | AttributeUsageAttribute Class

Retrieving Custom Attributes

You can retrieve custom attributes using the **GetCustomAttribute** or **GetCustomAttributes** methods of the **System.Attribute** class.

To retrieve a single instance of a custom attribute from a class

1. Add an **Imports** statement to the top of your source code to import the **Attribute** class from the **System** namespace:

```
Imports System.Attribute
```

2. Create a procedure to retrieve the attribute:

```
Sub RetrieveAttribute

End Sub
```

3. Inside the procedure, declare a variable of type **Attribute**, and another variable of the same type as the attribute you wish to retrieve:

```
Dim Attr As Attribute
Dim CustAttr As CustomAttribute
```

4. Use the **GetType** operator to pass the type of the class and attribute to a call to the **GetCustomAttribute** method, and then assign the returned value to the variable declared as **Attribute**:

```
Attr = GetCustomAttribute(GetType(ThisClass), _
                          GetType(CustomAttribute), False)
```

5. Use the **CType** function to convert the attribute's data type from generic attribute to the specific attribute of the type you retrieved. Then assign the result to the variable declared as the custom attribute type:

```
CustAttr = CType(Attr , CustomAttribute)
```

6. Check to see if the attribute was retrieved using **IsNothing**, and if it was, use the fields, properties, and methods of the attribute:

```
If CustAttr Is Nothing Then
   MsgBox("The attribute was not found.")
Else
   'Get the label and value from the custom attribute.
   MsgBox("The attribute label is: " & CustAttr.Label)
   MsgBox("The attribute value is: " & CustAttr.Value)
   End If
```

In the above example, the **GetAttr** procedure calls the **GetCustomAttribute** method of the **System.Attribute** class to get the custom attribute applied to the class `ThisClass`. **GetCustomAttribute** is a shared method, so you do not need to create an instance of **System.Attribute** first. The **CType** function converts the returned attribute from type **System.Attribute** to the custom attribute type `CustomAttribute`.

See Also

Attribute.GetCustomAttribute Method | Attribute.GetCustomAttributes Method | GetType Operator | CType Function | IsNothing Function | GetAttr Function | Defining Your Own Attributes | Application of Attributes | Retrieving Information Stored in Attributes | AttributeUsageAttribute Class

Examples of Custom Attribute Usage

The following example defines a custom attribute that can be applied only to classes:

```
<AttributeUsage(AttributeTargets.Class)> Public Class CustomAttribute
      Inherits System.Attribute

      'Declare two private fields to store the property values.
      Private m_Label As String
      Private m_Value As Integer

      'The Sub New constructor is the only way to set the properties.
      Public Sub New(ByVal _Label As String, ByVal _Value As Integer)
         m_Label = _Label
         m_Value = _Value
      End Sub

      Public Overridable ReadOnly Property Label() As String
         Get
            Return m_Label
         End Get
      End Property

      Public Overridable ReadOnly Property Value() As Integer
         Get
            Return m_Value
         End Get
      End Property
   End Class
```

Only the constructor for the attribute class can set the properties defined in this attribute. The following code shows how you could use the attribute:

```
' Apply the custom attribute to this class.
<Custom("Some metadata", 66)> Class ThisClass
   ' Add class members here.
End Class
```

Declared Elements

A *declared element* is a programming element that is defined in a declaration statement. Declared elements include variables, constants, enumerations, structures, properties, methods, procedures, procedure arguments, function returns, events, delegates, interfaces, and classes. Declaration statements include **Dim**, **Const**, **Public**, **Protected**, **Friend**, **Protected Friend**, **Private**, **Static**, **Sub**, **Function**, **Property**, **Structure**, **Enumeration**, **Class**, and **Interface**.

In This Section

Declared Element Names
Describes how to name elements and use alphabetic case.
Declared Element Characteristics
Covers characteristics, such as scope, possessed by declared elements.
Declared Element Reference
Describes how the compiler matches a reference to a declaration and how to qualify a name.

Related Sections

Covers object-oriented programming basics.
Program Structure and Code Conventions
Presents guidelines for making your code easier to read, understand, and maintain.
Declaration Statements
Describes statements that name and define procedures, variables, arrays, and constants.

Declared Element Names

Every declared element has a name, also called an *identifier*, which is what the code uses to refer to it.

An element name:

- Must begin with an alphabetic character or an underscore (_).
- Must contain only alphabetic characters, decimal digits, and underscores.
- Must contain at least one alphabetic character or decimal digit it if begins with an underscore.
- Must not be more than 1023 characters long.

The following example shows some valid and invalid element names:

```
aB123__45   ' Valid.
_567   ' Valid.
_   ' Invalid - consists of an underscore only.
12ABC   ' Invalid - begins with a decimal digit.
xyz$wv   ' Invalid - contains an identifier type character.
```

> **Note** The length limit of 1023 characters also applies to a fully qualified name, such as: `OuterNamespace.MiddleNamespace.InnerNamespace.ThisClass.ThisElement`. The entire preceding string is limited to 1023 characters.

Escaped Names

Generally, an element name must not match any of the keywords reserved by Visual Basic, such as **Case** or **Friend**. However, you can define an *escaped name*, which is enclosed by brackets ([ ]). An escaped name can match any Visual Basic keyword, since the brackets remove any ambiguity. You also use the brackets when you refer to the name later in your code.

Case Sensitivity in Names

Names in Visual Basic .NET are case insensitive. This means that when the compiler compares two names that differ in alphabetic case only, it interprets them as the same name. For example, `ABC` and `abc` are considered to refer to the same declared element.

However, the common language runtime uses case-sensitive binding. Therefore, when you produce an assembly or a DLL and make it available to other assemblies, your names are no longer case insensitive. For example, if you define a class with an element called `ABC`, and other assemblies make use of your class through the common language runtime, they must refer to the element as `ABC`. If you subsequently recompile your class and change the element's name to `abc`, the other assemblies using your class can no longer access that element. Therefore, when you release an updated version of an assembly, you should not change the alphabetic case of any public elements.

Comparison of names is also independent of locale; that is, if two names match in one locale, they are guaranteed to match in all locales.

Declared Element Characteristics

A *characteristic* of a declared element is an aspect of that element that affects how code can interact with it. Every declared element has one or more of four characteristics — data type, lifetime, scope, and accessibility — associated with it.

In This Section

Characteristics of Visual Basic Declared Elements
Presents a list of all Visual Basic declared elements and the characteristics associated with each.
Lifetime
Explains how lifetimes are determined, how they begin and end, and how they can be extended.
Scope
Describes the different levels of scope a programming element can have.
Accessibility
Describes the different levels of accessibility a programming element can have.

Related Sections

Data Types
Describes the kinds of data that programming elements can hold and how that data is stored.
Variable Declaration
Explains how to specify the name and characteristics of a variable.

Characteristics of Visual Basic Declared Elements

Every *declared element* (a programming element that is defined in a declaration statement) has one or more of the following characteristics associated with it:

- Data type — the values the element can hold, and how those values are stored
- Lifetime — the period of execution time during which the element is available for use
- Scope — the set of all code that can refer to the element without qualifying its name
- Accessibility — the permission for code to make use of the element

The following table shows the declared elements and the characteristics that apply to each one.

Element	**Data Type**	**Lifetime**	**Scope**	**Accessibility**
Variable	Yes	Yes	Yes	Yes
Constant	Yes	No	Yes	Yes
Enumeration	Yes	No	Yes	Yes
Structure	No	No	Yes	Yes
Property	Yes	No	Yes	Yes
Method	No	No	Yes	Yes
Procedure	No	No	Yes	Yes
Procedure argument	Yes	Yes	Yes	No
Function return	Yes	Yes	Yes	No
Event	No	No	Yes	Yes
Delegate	No	No	Yes	Yes
Interface	No	No	Yes	Yes
Class	No	No	Yes	Yes

Visibility

The concept of visibility is often mentioned. Visibility results from a combination of lifetime, scope, and accessibility. A programming element can be said to be *visible* from a block of code when all three of the following conditions apply:

- The element is within its lifetime — that is, it has been created and not yet terminated.
- The scope of the element includes the block of code referring to it.
- The element's accessibility permits the code to use it.

See Also

Lifetime | Scope | Accessibility

Lifetime

The *lifetime* of a declared element is the period of time during which it is available for use. Variables are the only elements that have lifetime; for this purpose, the compiler treats procedure arguments and function returns as special cases of variables. The lifetime of a variable represents the period of time during which it can hold a value. Its value can change over its lifetime, but it always holds some value.

Different Lifetimes

A variable declared at module level typically exists for the entire time your application is running. A nonshared variable declared in a class or structure exists as a separate copy for each instance of the class or structure in which it is declared; each such variable has the same lifetime as its instance. However, a **Shared** variable has only a single lifetime, which lasts for the entire time your application is running.

Local variables declared with **Dim** exist only while the procedure in which they are declared is executing. This applies also to that procedure's arguments and to any function return. However, if that procedure calls other procedures, the local variables retain their values while the called procedures are running.

Beginning of Lifetime

A local variable's lifetime begins when execution enters the procedure in which it is declared. Every local variable is initialized to the default value for its data type as soon as the procedure begins execution. Numeric variables (including **Byte** and **Char**) are initialized to zero, **Date** variables to midnight of January 1 of the year 1, **Boolean** variables to **False**, and reference type variables (including strings, arrays, and **Object**) to **Nothing**.

Each member of a structure variable is initialized as if it were a separate variable. Similarly, each element of an array variable is initialized individually.

If a variable is declared with an initializer, the specified value is assigned to the variable when its declaration statement is executed, as shown in the following example:

```
Dim X As Double = 18.973   ' X had previously been initialized to 0.
```

Variables declared within a block inside a procedure are initialized to their default values on entry to the procedure. These initializations take effect whether or not the block is ever executed.

End of Lifetime

When a procedure terminates, the values of its local variables are not preserved, and the memory used by the local elements is reclaimed. The next time the procedure is executed, all its local elements are created afresh and the local variables are initialized.

When an instance of a class or structure terminates, its nonshared variables lose their values. Each new instance of the class or structure creates all its nonshared elements and initializes the nonshared variables. **Shared** elements are preserved until your application stops running.

Extension of Lifetime

If a local variable is declared with the **Static** keyword, its lifetime is longer than the execution time of the procedure in which it is declared. If the procedure is inside a module, the static variable survives as long as your application continues running.

If a static variable is declared in a procedure inside a class, the variable's lifetime depends on whether the procedure is shared. If the procedure is declared with the **Shared** keyword, the variable's lifetime continues until your application terminates. If the procedure is nonshared, its static variables are instance members of the class, and their lifetimes are the same as that of the class instance.

In the following example, the `RunningTotal` function calculates a running total by adding a new value to the total of previous values stored in the static variable `ApplesSold`:

```
Function RunningTotal(ByVal Num As Integer) As Integer
   Static ApplesSold As Integer
   ApplesSold = ApplesSold + Num
   Return ApplesSold  ' ApplesSold keeps its current value.
End Function
```

If `ApplesSold` had been declared without using **Static**, the previous accumulated values would not be preserved across calls to the function, and the function would simply return the same value with which it was called.

You can produce the same lifetime by declaring `ApplesSold` at module level. If you change the scope of a variable this way, however, the procedure no longer has exclusive access to it. Because other procedures can access the variable and change its value, the running total would be unreliable and the code could be more difficult to maintain.

Static Variable Initialization | Declared Element Names | Declared Element Reference | Characteristics of Visual Basic Declared Elements | Scope | Accessibility | Variables | Variable Declaration | Dim Statement | Shared | Static | Nothing

Static Variable Initialization

You can initialize the value of a static local variable as part of its declaration. If you declare an array to be **Static**, you can initialize its rank (number of dimensions), the length of each dimension, and the values of the individual elements.

You can declare static variables with the same name in more than one procedure. If you do this, the Visual Basic compiler considers each such variable to be a separate element. The initialization of one of these variables does not affect the values of the others. The same applies if you define a procedure with a set of overloads and declare a static variable with the same name in each overload.

You can declare a static local variable in a class, that is, inside a procedure in that class. However, you cannot declare a static local variable in a structure.

Characteristics of Visual Basic Declared Elements | Declared Element Characteristics | Lifetime | Scope | Accessibility | Variables | Variable Declaration | Procedure Overloading | Static

Scope

The *scope* of a declared element is the set of all code that can refer to it without qualifying its name or making it available through an **Imports** statement. An element can have scope at one of the following levels:

- Block scope — available only within the code block in which it is declared
- Procedure scope — available only within the procedure in which it is declared
- Module scope — available to all code within the module, class, or structure in which it is declared
- Namespace scope — available to all code in the namespace

These levels of scope progress from the narrowest (block) to the widest (namespace), where *narrowest scope* means the smallest set of code that can refer to the element without qualification.

You specify the scope of an element when you declare it. The scope can depend on the following factors:

- The region (block, procedure, module, class, or structure) in which you declare the element
- The namespace containing the element's declaration
- The accessibility you declare for the element

Use care when you define variables with the same name but different scope, because doing so can lead to unexpected results. For more information, see Reference Matching.

See Also

Levels of Scope | Imports Statement | Reference Matching

Levels of Scope

A programming element is available throughout the region in which you declare it. All code in the same region can refer to the element without qualifying its name.

Block Scope

A block is a set of statements terminated by an **End**, **Else**, **Loop**, or **Next** statement, for example within a **For...Next** or **If...Then...Else...End If** construction. An element declared within a block can be used only within that block. In the following example, the scope of the integer variable `Cube` is the block between **If** and **End If**, and `Cube` can no longer be referenced when execution passes out of the block:

```
If N < 1291 Then
   Dim Cube As Integer
   Cube = N ^ 3
End If
```

> **Note** Even if the scope of an element is limited to a block, its lifetime is still that of the entire procedure. If you enter the block more than once during the procedure, a block variable retains its previous value. To avoid unexpected results in such a case, it is wise to initialize the variable each time.

Procedure Scope

An element declared within a procedure is not available outside that procedure. Only the procedure that contains the declaration can use it. Elements at this level are also known as *local* elements. You declare them with the **Dim** statement, with or without the **Static** keyword.

Procedure and block scope are closely related. If an element is declared inside a procedure but outside any block within that procedure, the element can be thought of as having block scope, where the block is the entire procedure.

> **Note** All local elements, even if they are **Static** variables, are private to the procedure in which they appear. You cannot declare an element using the **Public** keyword within a procedure.

Module Scope

For convenience, the single term *module level* applies equally to modules, classes, and structures. You can declare elements at this level by placing the declaration statement outside of any procedure or block within the module, class, or structure.

When you make a declaration at the module level, the accessibility you choose determines the scope. The namespace that contains the module, class, or structure also affects the scope.

Elements for which you declare **Private** accessibility are available for reference to every procedure in that module, but not to any code in a different module. The **Dim** statement at module level defaults to **Private** if you do not use any accessibility keywords. However, you can make the scope and accessibility more obvious by using the **Private** keyword in the **Dim** statement.

In the following example, the string variable `strMsg` is available to all procedures defined in the module. When the second procedure is called, it displays the contents of the string variable `strMsg` in a dialog box:

```
' Put the following declaration at module level (not in any procedure).
Private strMsg As String
' ...
Sub InitializePrivateVariable()
   strMsg = "This variable cannot be used outside this module."
End Sub
' ...
Sub UsePrivateVariable()
   MsgBox(strMsg)
End Sub
```

Namespace Scope

If you declare an element at module level using the **Friend** or **Public** keyword, it becomes available to all procedures throughout the namespace in which the element is declared. With the following alteration to the preceding example, the string variable

`strMsg` can be used by code anywhere in the namespace of its declaration:

```
' Include this declaration at module level (not inside any procedure).
Public strMsg As String   ' strMsg is available throughout the namespace.
```

Namespace scope includes nested namespaces. An element available from within a namespace is also available from within any namespace nested inside that namespace.

If your project does not contain any **Namespace** statements, everything in the project is in the same namespace. In this case, namespace scope can be thought of as project scope. **Public** elements in a module, class, or structure are also available to any project that references their project.

See Also

Accessibility

The *accessibility* of a declared element is the ability to use it, that is, the permission for code to read it or write to it. This is determined not only by how you declare the element itself, but also by the accessibility of the element's container. If the containing element is not accessible, none of its contained elements are accessible, even those declared as **Public**. For example, a **Public** variable in a **Private** structure is accessible from inside the class containing the structure, but not from outside that class.

Public

The **Public** keyword in the **Dim** statement declares elements to be accessible from anywhere within the same project, from other projects that reference the project, and from an assembly built from the project. The following code shows a sample **Public** declaration:

```
Public Class ClassForEverybody
```

You can use **Public** only at module, namespace, or file level. This means you can declare a public element in a source file or inside a module, class, or structure, but not within a procedure.

Protected

The **Protected** keyword in the **Dim** statement declares elements to be accessible only from within the same class, or from a class derived from this class. The following code shows a sample **Protected** declaration:

```
Protected Class ClassForMyHeirs
```

You can use **Protected** only at class level, and only when declaring a member of a class.

Friend

The **Friend** keyword in the **Dim** statement declares elements to be accessible from within the same project, but not from outside the project. The following code shows a sample **Friend** declaration:

```
Friend StringForThisProject As String
```

You can use **Friend** only at module, namespace, or file level. This means you can declare a friend element in a source file or inside a module, class, or structure, but not within a procedure.

Protected Friend

The **Protected** and **Friend** keywords together in the **Dim** statement declare elements to be accessible either from derived classes or from within the same project, or both. The following code shows a sample **Protected Friend** declaration:

```
Protected Friend StringForProjectAndHeirs As String
```

You can use **Protected Friend** only at class level, and only when declaring a member of a class.

Private

The **Private** keyword in the **Dim** statement declares elements to be accessible only from within the same module, class, or structure. The following code shows a sample **Private** declaration:

```
Private NumberForMeOnly As Integer
```

You can use **Private** only at module, namespace, or file level. This means you can declare a private element in a source file or inside a module, class, or structure, but not within a procedure.

> **Note** At the module level, the **Dim** statement without any accessibility keywords is equivalent to a **Private** declaration. However, you might want to use the **Private** keyword to make your code easier to read and interpret.

Declared Element Reference

When your code makes reference to a declared element, the Visual Basic compiler matches the name in your reference to the appropriate declaration of that name. If more than one element is declared with the same name, you can control which of those elements is referenced by *qualifying* its name.

Qualifying a name means preceding it in your source statement with information that resolves any possible ambiguity. Qualifying information can include one or more namespaces, a class, a structure, or a module. In the following example, the **Sub** procedure `SomeSub` is declared in more than one place, and the **Call** statement specifies that the procedure that should be called is the one defined in the module `SomeMod` in the namespace `SomeSpace`:

```
Call SomeSpace.SomeMod.SomeSub()   ' SomeSub is qualified.
```

Procedures
Describes **Sub**, **Function,** and **Property** procedures, as well as advanced topics such as recursive and overloaded procedures.

Reference Matching

When the compiler matches a name reference to a name declaration, it uses the matching declaration with the narrowest scope. In the following example, two **Sub** procedures, both called `Perform`, are declared **Public** in different modules in a project. Each one can be specified without qualification within its own module but must be qualified if referenced from anywhere else.

```
' Assume these three modules are all in the same project.
Module Mod1
   Public Sub Perform()  ' Public keyword allows access outside of Mod1.
      ' ...
      MsgBox("Mod1.Perform() now returning")
   End Sub
End Module

Module Mod2
   Public Sub Perform()   ' Might be different from Perform() in Mod1.
      ' ...
      MsgBox("Mod2.Perform() now returning")
   End Sub
   Public Sub DoSomething()
      Perform()   ' Calls Perform in Mod2, the active module.
      Mod1.Perform()   ' Calls Perform in Mod1.
   End Sub
End Module

Module Mod3
   Public Sub CallPerform()
      Perform()   ' This call is ambiguous and generates an error.
      Mod1.Perform()   ' Calls Perform in Mod1.
   End Sub
End Module
```

Members of Other Classes and Structures

When you use a nonshared member of another class or structure, you must first qualify the member name with a variable or expression that points to an instance of the class or structure. In the following example, `DemoClass` is an instance of a class named `Class1`:

```
Dim DemoClass As Class1 = New Class1()
DemoClass.SomeSub[(argumentlist)]
```

You cannot use the class name itself to qualify a member that is not **Shared**. The instance must first be declared as an object variable (in this case `DemoClass`) and then referenced by the variable name.

You can qualify a **Shared** member of a class either with the class name or with a variable or expression that points to an instance of the class.

References

To use **Public** elements defined in another project, you must first set a *reference* to that project's assembly or type library. You can set a reference by choosing **Add Reference** from the **Project** menu, or with the **/reference** command-line compiler option.

For example, you can use the XML object model of .NET. If you set a reference to the **System.Xml** namespace, you can declare and use any of its classes, such as **XmlDocument**. The following declaration provides an example:

```
Dim XDoc As System.Xml.XmlDocument   ' XDoc is an XML document object.
```

Imports

You can use the **Imports** statement to *import* the namespaces containing the modules or classes you want to use. This allows you to refer to the elements defined in an imported namespace without qualifying their names. In the preceding example, you could import the namespace containing the **XmlDocument** class, as follows:

```
Imports System.Xml   ' Make System.Xml available without qualification.
' The Imports statement must precede all your declarations.
Dim XDoc As XmlDocument   ' XDoc is an XML document object.
```

In addition, the **Imports** statement can define an *import alias* for each imported namespace. This can make your source code shorter and easier to read. In the preceding example, you could import with an alias, as follows:

```
Imports XD = System.Xml   ' XD is alias for System.Xml namespace.
' The Imports statement must precede all your declarations.
Dim XDoc As XD.XmlDocument   ' XDoc is an XML document object.
```

The **Imports** statement does not make elements from other projects available to your application; that is, it does not take the place of setting a reference. Importing a namespace simply removes the need to qualify the names defined in that namespace.

You can also use the **Imports** statement to import modules, classes, structures, and enumerations. You can then use the members of such imported elements without qualification. However, nonshared members of classes and structures must always be qualified with a variable or expression that evaluates to an instance of the class or structure.

Classes with the Same Name

When you create a new instance of an object, you might have to qualify the class with the namespace or type library to which it belongs. For example, the **System.Windows.Forms** and **System.Web.UI.WebControls** namespaces both contain a **Label** class. If your application uses both, or if it defines its own **Label** class, you must distinguish the different **Label** objects. Include the namespace or import alias in the variable declaration, as in the following example:

```
Imports WIN = System.Windows.Forms, WEB = System.Web.UI.WebControls
' The Imports statement must precede all your declarations.
Dim WinLabel As New WIN.Label()   ' Uses the Windows.Forms.Label class.
```

Shadowing

When two programming elements share the same name, one of them can hide, or *shadow*, the other one. In such a situation, the shadowed element is not available for reference; instead, when your code uses the shared name, the Visual Basic compiler resolves it to the shadowing element.

An element can shadow another element in two different ways. The shadowing element can be declared inside a subregion of the region containing the shadowed element, in which case the shadowing is accomplished through scope. Or a deriving class can redefine a member of a base class, in which case the shadowing is done through inheritance.

Shadowing Through Scope

It is possible for programming elements in the same module, class, or structure to have the same name but different scope. When two elements are declared in this manner and the code refers to the name they share, the element with the narrower scope shadows the other element (block scope is the narrowest).

For example, a module can define a **Public** variable named `Temp`, and a procedure within the module can declare a local variable also named `Temp`. References to `Temp` within the procedure access the local variable, while references to `Temp` outside the procedure access the **Public** variable. In this case, the procedure variable `Temp` shadows the module variable `Temp`.

When it is shadowed by a local variable, a module variable is still accessible from within a procedure by qualifying the variable with the name of the module, class, or structure it is declared in, as illustrated in the following example:

```
Module Mod4
   Public Num As Integer   ' This Num is a module-level variable.

   Sub Show()
     Dim Num As Integer   ' This Num is a local variable.
     Num = 2   ' Local Num has a value of 2.
     MsgBox(CStr(Mod4.Num))   ' Mod4.Num has a value of 1.
   End Sub

   Sub UseModuleLevelNum()
      Num = 1   ' Set module-level Mod4.Num to 1.
      ' ...
      Show()   ' Call Show, which displays module-level Num.
   End Sub
End Module
```

Shadowing Through Inheritance

If a derived class redefines a programming element inherited from a base class, the redefining element shadows the original element. You can shadow any type of declared element, or set of overloaded elements, with any other type. For example, an **Integer** variable can shadow a **Function** procedure. If you shadow a procedure with another procedure, you can use a different argument list and a different return type.

> **Note** If the shadowing element is not accessible from the consuming code, for example if it is declared **Private**, shadowing is defeated and the compiler resolves any reference to the same element it would have if there had been no shadowing. This is the accessible element the fewest derivational steps backward from the shadowing class. If the shadowed element is a procedure, the resolution is to the proximate accessible version with the same name, argument list, and return type.

Do not confuse shadowing with overriding. Both are used when a derived class inherits from a base class, and both redefine one declared element with another. But there are differences between the two. The following table compares shadowing with overriding:

Criterion	Shadowing	Overriding
Purpose	Protecting against a subsequent base class modification introducing a member you hav e already defined in your derived class	Achieving polymorphism by defining a different im plementation of a procedure or property with the s ame calling sequence
Redefined element	Any declared element type	Only a procedure (**Function** or **Sub**) or property
Redefining element	Any declared element type	Only a procedure or property with the identical call ing sequence[1]

Accessibility	Any accessibility	Cannot expand the accessibility of overridden element (for example, cannot override **Protected** with **Public**)
Readability and writability	Any combination	Cannot change readability or writability of overridden property
Keyword usage	**Shadows** recommended in derived class; **Shadows** assumed if neither **Shadows** nor **Overrides** specified	**Overridable** required in base class; **Overrides** required in derived class
Inheritance of redefining element by classes deriving from your derived class	Shadowing element inherited by further derived classes; shadowed element still hidden[2]	Overriding element inherited by further derived classes; overridden element still overridden

[1] The calling sequence consists of the element type (**Function**, **Sub**, or **Property**), name, argument list, and return type. You cannot override a procedure with a property, or the other way around. You cannot override a **Function** procedure with a **Sub** procedure, or the other way around.

[2] If the shadowing element is inaccessible in a further derived class, shadowing is not inherited. For example, if you declare the shadowing element as **Private**, a class deriving from your derived class inherits the original element instead of the shadowing element.

When you access an element from a derived class, you normally do so through the current instance of that derived class, by qualifying the element name with the **Me** keyword. If your derived class shadows the element in the base class, you can access the base class element by qualifying it with the **MyBase** keyword.

How you access a derived class can affect whether your code uses a shadowing element or the element it shadows. In the following example, the variable `BasObj` is declared as the base class. Assigning a `DervCls()` object to it constitutes a widening conversion and is therefore valid. However, the base class cannot access the shadowing version of the variable `Z` in the derived class, so the compiler resolves `BasObj.Z` to the original base class value.

```
Public Class BaseCls
   Public Z As Integer = 100   ' The element to be shadowed.
End Class
Public Class DervCls
   Inherits BaseCls
   Public Shadows Z As String = "*"   ' The shadowing element.
End Class
Public Class UseClasses
   Dim BObj As BaseCls = New DervCls()   ' DervCls widens to BaseCls.
   Dim DObj As DervCls = New DervCls()   ' Access through derived class.
   Public Sub ShowZ()
      MsgBox("Accessed through base class: " & BObj.Z)   ' Outputs 100.
      MsgBox("Accessed through derived class: " & DObj.Z)   ' Outputs "*".
   End Sub
End Class
```

Note If you shadow the same base class element with more than one element in your derived class, the shadowing elements become overloaded versions.

Names in Forms and Controls

In a form, all properties, controls, variables, constants, and procedures are members at the module level. Because all form members are in the same scope, no two of them are allowed to have the same name.

For each control, the forms designer automatically generates a variable at module level with the name of the control. Therefore, you cannot declare another variable at module level with the same name.

Within a form module, local variables with the same names as controls on the form shadow those controls. You must qualify the control with a reference to the form or with the **Me** keyword to access any of its properties.

For information on defining two programming elements with the same name, see Name Ambiguity.

See Also

Name Ambiguity | Declared Element Reference | Choice of Variable Scope | Me | Shadowing

Name Ambiguity

When you define two or more programming elements with the same name, a *name ambiguity* can result when the compiler attempts to resolve a reference to that name. For example, if you define two modules, each containing a **Public Function** procedure called `Recalculate`, and call `Recalculate` from a third module without qualifying its name, the compiler generates an error message because it cannot resolve the reference.

You can avoid name ambiguity by giving all your elements unique names. Then you can call any procedure without needing to qualify its name with a namespace or module.

You can resolve name ambiguity by qualifying each name with the appropriate module name and, if necessary, a namespace name. The following example calls the **Sub** procedure `YourSub` and passes `MyVar` as an argument:

```
YourProject.YourModule.YourSub(MyProject.MyModule.MyVar)
```

You can use as many levels of qualifiers as necessary to differentiate identical names.

For more information on names, see Names in Forms and Controls.

Names in Forms and Controls | Declared Element Reference | Reference Matching

Data Types

The *data type* of a programming element refers to what kind of data it can hold and how that data is stored. Data types apply to all values that can be stored in computer memory or participate in the evaluation of an expression. Every variable, literal, constant, property, procedure argument, and procedure return value has a data type.

A *declared data type* is specified as part of the declaration of a programming element. Unless you use typeless programming, you must declare data types for all your programming elements.

This section describes the declaration and use of Visual Basic .NET data types.

In This Section

Data Type Declaration
Covers declaring data types of various programming elements.
Elementary Data Types
Discusses numeric, character, and miscellaneous types provided by Visual Basic.
Composite Data Types
Summarizes structures, arrays, and classes as data types.
Data Type Implementation
Illustrates how Visual Basic .NET classifies and implements various data types.
Type Conversions
Explains changing between data types, classifications of conversions, special considerations.
Structures: Your Own Data Types
Discusses structures, how to declare them, and how to use them.
Typeless Programming
Provides an overview of programming without declaring data types, type semantics.

Related Sections

Data Type Summary
Lists the elementary data types supplied by Visual Basic .NET.

Data Type Declaration

Every programming element that can hold data has a declared data type. The following list shows how to specify data types of various elements:

- Variable — In a declaration statement; see Data Types in Declaration Statements
- Literal — With a literal type character; see Type Characters
- Constant — In a declaration statement; see Data Types in Declaration Statements

Data Type Summary
Covers elementary data types supplied by Visual Basic .NET.

Data Types in Declaration Statements

You define a variable or constant with a declaration statement, and you specify its data type with the **As** clause. The declaration statements are **Dim** and **Const**, and the keywords they can use are **Public**, **Protected**, **Friend**, **Private**, **Shared**, and **Static**. Note that **Protected** can be used only on elements being declared within a class.

The following statements demonstrate ways to declare variables:

```
Private I As Integer
Dim Amount As Double
Static YourName As String
Public BillsPaid As Decimal
```

To declare a constant, use **Const** in the declaration, as in the following example:

```
Const Modulus As Single = 4.17825  ' Value cannot be changed.
```

You can declare several variables in a single declaration statement, provided they all have the same accessibility. The following statements demonstrate multiple variable declaration:

```
Public I, J, K As Integer   ' Declare three integer variables.
Dim FirstName, MiddleName, LastName As String   ' Three String variables.
Private S, SArray() As Short   ' One Short variable and one Short array.
Friend B1, B2 As Byte, C1, C2 As Char   ' Two Byte and two Char variables.
```

Type Characters

In addition to specifying a data type in a declaration statement, you can force the data type of some programming elements with a *type character*. The type character must immediately follow the element name, with no intervening characters of any kind.

The type character is not part of the name of the element. An element defined with a type character can be referenced without the type character.

Identifier Type Characters

Visual Basic supplies a set of *identifier type characters*, which you can use in a declaration to specify the data type of a variable or constant. The following table shows the available identifier type characters with examples of usage.

Identifier type character	Data type	Example
%	**Integer**	`Dim L%`
&	**Long**	`Public M&`
@	**Decimal**	`Const W@ = 37.5`
!	**Single**	`Dim Q!`
#	**Double**	`Static X#`
$	**String**	`Private V$ = "Secret"`

No identifier type characters exist for the **Boolean**, **Byte**, **Char**, **Date**, **Object**, or **Short** data types, or for any composite data types.

Identifier type characters also can force the data type of other identifiers, and you can even use them in expressions. In some cases, you can append the **$** character to a Visual Basic function, for example **Left$** instead of **Left**.

In all cases, the identifier type character must immediately follow the identifier.

Literal Type Characters

A *literal* is a textual representation of a particular value of a type. The form of a literal as it appears in your code usually determines its data type. The compiler treats integral literals as **Integer** unless they are large enough to be **Long**, and it treats nonintegral literals as **Double**. In the following statements, the data type of the literal is not ambiguous:

```
J = 347    ' This literal is of the Integer data type.
X = 9.2    ' This literal is of the Double data type.
B = False  ' This literal is of the Boolean data type.
```

Visual Basic supplies a set of *literal type characters*, which you can use to force a literal to assume a data type other than the one its form indicates. You do this by appending the character to the end of the literal. The following table shows the available literal type characters with examples of usage.

Literal type character	Data type	Example
S	**Short**	`I = 347S`

I	**Integer**	`J = 347I`
L	**Long**	`K = 347L`
D	**Decimal**	`H = 347D`
F	**Single**	`Y = 347F`
R	**Double**	`Z = 347R`
C	**Char**	`Q = "."C`

No literal type characters exist for the **Boolean**, **Byte**, **Date**, **Object**, or **String** data types, or for any composite data types.

Literals can also use the identifier type characters (**%**, **&**, **@**, **!**, **#**, **$**), as can variables, constants, and expressions. However, the literal type characters (**S**, **I**, **L**, **D**, **F**, **R**, **C**) can be used only with literals.

In all cases, the literal type character must immediately follow the literal.

Data Type Summary
Provides an overview of the elementary data types supplied by Visual Basic .NET.

Numeric Data Types

Visual Basic supplies several numeric data types for handling numbers in various representations. Integral types represent only whole numbers, and nonintegral types represent numbers with both integer and fractional parts.

In This Section

Integral Types
Discusses using **Short**, **Integer**, **Long**, and **Byte** to represent integers.
Nonintegral Types
Discusses using **Decimal**, **Single**, and **Double** to represent numbers with both integer and fractional parts.

Data Type Implementation
Describes how Visual Basic .NET classifies and implements various data types.
Type Conversions
Explains changing between data types, classifications of conversions, special considerations.

Integral Types

Integral data types are those that represent only whole numbers. The signed integral data types are **Short** (16-bit), **Integer** (32-bit), and **Long** (64-bit). If a variable always stores whole numbers rather than numbers with a fractional amount, declare it as one of these types.

The unsigned integral type is **Byte** (8-bit). If a variable contains binary data, or data of unknown nature, declare as this type. If more than eight bits of data are needed, declare the variable as an array of **Byte** elements.

Arithmetic operations are faster with integral types than with other data types. They are fastest with the **Integer** type in Visual Basic .NET. Integral types are especially useful as counter variables in **For ... Next** loops.

Since **Byte** is an unsigned type with a range of 0-255, it cannot represent a negative number. If you use the unary minus (**-**) operator on an expression that evaluates to type **Byte**, Visual Basic converts the expression to **Integer** first.

If you try to set a variable of an integral type to a number outside the range for that type, an error occurs. If you try to set it to a fraction, the number is rounded, as in the following example:

```
Dim K As Integer  ' Valid range is -2147483648 to +2147483647.
' ...
K = 2147483648    ' Causes an error.
K = CInt(5.9)     ' Sets K to 6.
```

Binary data stored in **Byte** variables and arrays is preserved during format conversions. You should not use a **String** variable for binary data, because its contents can be corrupted during conversion between ANSI and Unicode formats. Such conversion can happen automatically when Visual Basic reads or writes files, or when it calls DLLs, methods, and properties.

For integral types, the literal type characters are **S** for **Short**, **I** for **Integer**, and **L** for **Long**. No literal type character exists for **Byte**.

See Also

Arrays | Introduction to International Applications in Visual Basic and Visual C# | Integer Data Type | Long Data Type | Short Data Type | Byte Data Type | Nonintegral Types

Nonintegral Types

Nonintegral data types are those that represent numbers with both integer and fractional parts. The nonintegral numeric data types are **Decimal** (128-bit fixed point), **Single** (32-bit floating point), and **Double** (64-bit floating point). They are all signed types. If a variable can contain a fraction, declare as one of these types.

The **Decimal** data type supports up to 29 significant digits and can represent values up to 7.9228×10^{28}. It is particularly suitable for calculations, such as financial, that require a large number of digits but cannot tolerate rounding errors.

To assign a large value to a **Decimal** variable or constant, you must append the literal type character to a numeric literal if it is too large for the **Long** data type, as the following example shows:

```
Dim DecVar As Decimal
DecVar = 9223372036854775808   ' Overflow; too big for Long data type.
DecVar = 9223372036854775808D  ' No overflow; Decimal data type.
```

Floating point (**Single** and **Double**) numbers have larger ranges than **Decimal** numbers but can be subject to rounding errors. Floating point types support fewer significant digits than **Decimal** but can represent values of greater magnitude.

Floating point values can be expressed as *mmm***E***eee*, in which *mmm* is the mantissa (the significant digits) and *eee* is the exponent (a power of 10). The highest positive value of a **Single** data type is 3.4028235E+38, and the highest positive value of a **Double** data type is 1.79769313486231570E+308.

For nonintegral types, the literal type characters are **D** for **Decimal**, **F** for **Single**, and **R** for **Double**.

Single Data Type | Double Data Type | Decimal Data Type | Integral Types

Character Data Types

Visual Basic provides *character data types* for dealing with printable and displayable characters. While they both deal with Unicode characters, **Char** holds a single character while **String** contains any number of characters.

Char Type

The **Char** data type is a single two-byte (16-bit) Unicode character. You can use methods like **IsDigit** and **IsPunctuation** on a **Char** variable to determine its Unicode classification.

Visual Basic does not convert directly between **Char** and the numeric types. You can achieve a type conversion with functions such as **AscW** and **ChrW**.

If the type checking switch (**Option Strict**) is on, you must append the literal type character to a single-character string literal to identify it as the **Char** data type, as the following example shows:

```
Option Strict On
 ' ...
Dim CharVar As Char
CharVar = "@"    ' Cannot convert String to Char with Option Strict On.
CharVar = "@"C   ' Successfully assigns single character to CharVar.
```

Keep in mind that the **Char** type is unsigned.

The literal type character for **Char** is **C**.

String Type

The **String** data type is a sequence of zero or more two-byte (16-bit) Unicode characters. If a variable always contains a character string and never a numeric value, declare it to be of type **String**, as in the following example:

```
Private S As String
```

You can then assign strings to this variable and manipulate it using string functions, as in the following example:

```
S = "Database"
S = Microsoft.VisualBasic.Left(S, 4)   ' Set S to "Data".
```

The **String** data type holds Unicode characters, each of which can have a value between 0 and 65,535. A **String** variable or argument is always a *variable-length string*, which grows or shrinks as you assign new data to it.

Strings are sometimes padded with leading or trailing spaces. The **Trim**, **LTrim**, and **RTrim** functions remove these spaces. You might find these functions useful when working with strings.

No literal type character exists for **String**. However, the compiler treats literals enclosed within double quotes (**" "**) as **String**.

Char Data Type | LTrim, RTrim, and Trim Functions | String Data Type

Miscellaneous Data Types

Visual Basic supplies several data types that are not oriented toward numbers or characters. Instead, they deal with specialized data such as yes/no and date/time values.

In This Section

Boolean Type
Discusses true and false values.
Date Type
Discusses date and time values.
Object Type
Explains the type that is a pointer to an object or data of any type.

Related Sections

Data Types
Introduces Visual Basic .NET data types and describes how to use them.
Data Type Summary
Provides an overview of the elementary data types supplied by Visual Basic .NET.

Boolean Type

The **Boolean** data type is an unsigned value that is interpreted as either **True** or **False**. If a variable can contain only true/false, yes/no, or on/off information, declare it as type **Boolean**.

The default value of **Boolean** is **False**. In the following example, `RunningVB` is a **Boolean** variable, which stores a simple yes/no setting.

```
Dim RunningVB As Boolean
' Check to see if program is running on VB engine.
If ScriptEngine = "VB" Then
   RunningVB = True
End If
```

No literal type character exists for **Boolean**.

See Also

Boolean Data Type

Date Type

The **Date** data type is a 64-bit (8-byte) signed integer. Each increment represents 100 nanoseconds of elapsed time since the beginning (12:00 AM) of January 1 of the year 1 in the Gregorian calendar. A variable or constant of the **Date** data type holds both the date and the time, as in the following example:

```
SomeDate = #8/13/2002 12:14 PM#
```

If you do not include a date in a date/time literal, Visual Basic sets the date part of the value to January 1, 0001. If you do not include a time in a date/time literal, Visual Basic sets the time part of the value to the start of the day, that is, midnight.

When you convert a numeric data type to **Date**, Visual Basic treats its value as a signed integer. If you attempt to convert a negative number, an error results.

No literal type character exists for **Date**. However, the compiler treats literals enclosed within number sign (**# #**) characters as **Date**.

See Also

Date Data Type

Object Type

The **Object** data type is a 32-bit (4-byte) address that points to an object within your application or in some other application. When you declare a variable as **Object**, you can subsequently use it to refer to any object recognized by your application, as in the following example:

```
Dim objDb As Object
Dim MyCollection As New Collection()
' ... Suppose MyCollection has now been populated.
objDb = MyCollection.Item(1)
```

When you declare an object variable, try to use a specific class rather than the generic **Object**, for example **Database** instead of **Object** in the preceding example. You should also use the most specific class available, such as **TextBox** instead of **Control**, so that you can access its properties and methods. You can usually use the **Classes** list in the **Object Browser** to find available class names.

Variables of the **Object** data type can also point to data of any type. This means you can assign a variable, constant, or expression of any data type to an **Object** variable. To determine the data type an **Object** variable currently refers to, you can use the **GetTypeCode** method of the **Type** class, as in the following example:

```
Dim MyObject As Object
' ... Suppose MyObject has now had something assigned to it.
Dim DatTyp As Integer
DatTyp = Type.GetTypeCode(MyObject.GetType())
```

Programming elements declared as **Object** can accept values of any data type. **Object** is treated as a value type when holding a value type, and as a reference type when holding a reference type. In either case, an **Object** variable does not contain the value itself, but rather a pointer to the value. It always uses four bytes in computer memory, but this does not include the storage for the data representing the value of the variable. Because of the code that uses the pointer to locate the data, **Object** variables holding value types are slightly slower to access than explicitly typed variables.

No literal type character exists for **Object**.

Determining Inheritance

You can compare two objects to determine the relationship, if any, between the classes from which they are created. The **IsInstanceOfType** method of the **Type** class returns **True** if the current class inherits from the specified class, or if the current type is an interface supported by the specified class. The following example determines whether one object represents a class inherited from another object's class:

```
Public Class BaseClass
End Class
Public Class DerivedClass : Inherits BaseClass
End Class
Public Class TestTheseClasses
   Public Sub SeeIfRelated()
      Dim BaseObj As Object = New BaseClass()
      Dim DerivedObj As Object = New DerivedClass()
      Dim Related As Boolean
      Related = BaseObj.GetType().IsInstanceOfType(DerivedObj)
      MsgBox(CStr(Related))
   End Sub
End Class ' TestTheseClasses
```

Note the unexpected placement of the two object variables in the use of **IsInstanceOfType**. The supposed base type is used to generate the **Type** class, and the supposed derived type is passed as an argument to **IsInstanceOfType**.

Type Conversions | Object Variables | Type Class | Type.GetTypeCode Method | Type.IsInstanceOfType Method | Object Data Type

Composite Data Types

In addition to the elementary data types Visual Basic supplies, you can also assemble items of different types to create *composite data types* such as structures, arrays, and classes. You can build composite data types from elementary types and from other composite types. For example, you can define an array of structure elements, or a structure with array members.

A composite type is different from the data type of any of its components. For example, an array of **Integer** elements is not of the **Integer** data type.

There is no single data type comprising all structures. Instead, each definition of a structure represents a unique data type. The same uniqueness is true for classes.

There is also no single data type comprising all arrays. The data type of a particular instance of an array is determined by:

- The fact of being an array
- The rank (number of dimensions) of the array
- The element type of the array

In particular, the length of a given dimension is not part of the instance's data type. This is illustrated in the following example:

```
Dim A As Byte( ) = New Byte(12) {}
Dim B As Byte( ) = New Byte(100) {}
Dim C As Short( ) = New Short(100) {}
Dim D As Short( , )
Dim E As Short( , ) = New Short(4, 10) {}
```

In the preceding example, array variables `A` and `B` are considered to be of the same data type, even though they are initialized to different lengths. Array variables `B` and `C` are not of the same type because their element types are different. `C` and `D` are not of the same type because their ranks are different. `D` and `E` have the same type because their ranks and element types are the same, even though `D` is not yet initialized.

Data Type Implementation

The Visual Basic .NET data types can be classified according to whether a variable of a particular type stores its own data or a pointer to the data. This classification affects the way a data type is implemented.

In This Section

Value Types and Reference Types
Explains the difference between value and reference types, and which data types are which.
Data Types as Classes and Structures
Describes how Visual Basic data types are implemented in the underlying .NET Framework.

Related Sections

Data Types
Introduces the Visual Basic .NET data types and describes how to use them.
Data Type Summary
Lists the elementary data types supplied by Visual Basic .NET.

Value Types and Reference Types

A data type is a *value type* if it holds the data within its own memory allocation. A *reference type* contains a pointer to another memory location that holds the data.

Value types include:

- All numeric data types
- **Boolean**, **Char**, and **Date**
- All structures, even if their members are reference types
- 1Enumerations, since their underlying type is always **Byte**, **Short**, **Integer**, or **Long**

Reference types include:

- **String**
- All arrays, even if their elements are value types
- Class types, such as **Form**
- Delegates

You can assign either a reference type or a value type to a variable of the **Object** data type. An **Object** variable always holds a pointer to the data, never the data itself. However, if you assign a value type to an **Object** variable, it behaves as if it holds its own data.

You can find out whether an **Object** variable is acting as a reference type or a value type by passing it to the **IsReference** method on the **Information** class in the **Microsoft.VisualBasic** namespace. **Microsoft.VisualBasic.Information.IsReference** returns **True** if the content of the **Object** variable represents a reference type.

See Also

Data Types as Classes and Structures | Type Conversions | Structures: Your Own Data Types | Efficient Use of Data Types

Data Types as Classes and Structures

Every elementary data type in Visual Basic .NET is supported by a structure or a class in the **System** namespace. The compiler uses each data type keyword as an alias for the underlying structure or class. For example, declaring a variable with the reserved word **Byte** is the same as declaring it with the fully qualified structure name **System.Byte**.

The common language runtime also supports structures and classes that Visual Basic .NET does not supply. For example, the **System.UInt16**, **System.UInt32**, and **System.UInt64** structures provide the unsigned equivalents of **Short**, **Integer**, and **Long**. You can use these unsigned types to declare variables and constants, and you can access the methods .NET implements on these types. However, Visual Basic .NET does not support operations or type conversions involving types it does not supply.

In the .NET Framework, a structure is a value type and a class is a reference type. For this reason, value types such as **Char** and **Integer** are supported by .NET structures, while reference types such as **Object** and **String** are supported by .NET classes.

Since every reference type represents an underlying .NET class, you must use the **New** keyword when you initialize it. The following statement initializes an array:

```
Dim Totals() As Single = New Single(8) {}
```

You can also use the **New** keyword to initialize a value type. This is particularly useful if the type has a constructor that takes parameters.

Data Type Members

Because they are supported by .NET structures and classes, Visual Basic data types have members. These members include constructors, methods, properties, and fields. You can access the members (except the constructors) on a variable the same way you access methods and properties on an object. The following example uses the **Year**, **Month**, and **Day** properties and the **DaysInMonth** method of the **System.DateTime** structure to determine how many days are remaining in the current month:

```
Dim Current As Date   ' Date data type is supported by System.DateTime.
Dim DaysRemaining As Integer   ' Days remaining in current month.
' ...
Current = Now   ' Get current date/time into Current.
DaysRemaining = Date.DaysInMonth(Current.Year, Current.Month) - Current.Day
```

Note that you must qualify a reference to a data type member with either the name of the type (`Date`) or the name of a variable declared to be of that type (`Current`).

Data Type Member Examples

The following code prototypes illustrate some of the useful methods, properties, and fields on the data types:

```
<Char>.IsDigit()  ' Returns True if character is a numeric digit.
<Char>.IsLower()  ' Returns True if character is a lowercase letter.
<Date>.IsLeapYear()  ' Returns True if current year is a leap year.
<Date>.ToUniversalTime()  ' Returns local date/time converted to UTC.
<Double>.IsInfinity()  ' Returns True if contents represent infinity.
<Double>.IsNaN()  ' Returns True if contents are not a number (0/0).
<Long>.MaxValue  ' Constant representing largest positive Int64 value.
<Object>.GetType()  ' Returns Type object representing type of <Object>.
<Object>.GetType().GetTypeCode()  ' Returns type code of <Object>.
<String>.Chars(<index>)  ' Character at position <index> of <String>.
<String>.Length  ' Number of characters currently in <String>.
```

All numeric types, including **Byte** and **Char**, expose the **MaxValue** and **MinValue** public fields, which can be very useful when dealing with these types.

Data Type Member Equivalence

The .NET Framework also supplies a number of methods on data types that might appear to be equivalent to Visual Basic functions and keywords. For example, **System.Decimal.ToSingle()** performs the same type of action as the **CSng** keyword does on a **Decimal** expression. However, Visual Basic does not always use the .NET Framework methods to accomplish conversion or

other operations. **CSng** is not guaranteed to use **System.<*data type*>.ToSingle()**, and therefore the results are not guaranteed to be the same under marginal or boundary conditions.

Type Conversions

The process of changing a value from one data type to another type is called *conversion*. Conversions are either widening or narrowing, depending on the data capacities of the types involved. They are also implicit or explicit, depending on the syntax in the source code.

In This Section

Widening and Narrowing Conversions
Explains conversions classified by whether the destination type can hold the data.
Implicit and Explicit Conversions
Explains conversions classified by whether Visual Basic performs them automatically.
Value Changes During Conversions
Describes how converting to another data type can change the value or data representation.
Conversions Between Strings and Other Types
Illustrates converting between strings and numeric, **Boolean**, or date/time values.
Array Conversions
Steps you through the process of converting between arrays of different data types.

Related Sections

Data Types
Introduces the Visual Basic .NET data types and describes how to use them.
Data Type Summary
Lists the elementary data types supplied by Visual Basic .NET.

Widening and Narrowing Conversions

An important characteristic of a type conversion is whether the result of the conversion is within the range of the destination data type. A *widening conversion* changes a value to a data type that can accommodate any possible value of the original data. A *narrowing conversion* changes a value to a data type that might not be able to hold some of the possible values.

Widening Conversions

The following table shows the standard widening conversions.

Data type	Widens to data types
Byte	**Byte**, **Short**, **Integer**, **Long**, **Decimal**, **Single**, **Double**
Short	**Short**, **Integer**, **Long**, **Decimal**, **Single**, **Double**
Integer	**Integer**, **Long**, **Decimal**, **Single**, **Double**
Long	**Long**, **Decimal**, **Single**, **Double**
Decimal	**Decimal**, **Single**, **Double**
Single	**Single**, **Double**
Double	**Double**
Any enumerated type	Its underlying integer type and any type to which that widen s
Char	**Char**, **String**
Any type	**Object**
Any derived type	Any base type from which it is derived
Any type	Any interface it implements
Nothing	Any data type or object type

Conversions from **Integer** to **Single**, from **Long** to **Single** or **Double**, or from **Decimal** to **Single** or **Double**, might result in loss of precision, but never in loss of magnitude. In this sense they do not incur information loss.

It might seem surprising that a conversion from a derived type to one of its base types is widening. The justification is that the derived type contains all the members of the base type, so it qualifies as an instance of the base type. In the opposite direction, the base type does not have the members defined by the derived type.

Widening conversions always succeed and can always be performed implicitly.

Narrowing Conversions

The standard narrowing conversions include:

- The reverse directions of the widening conversions in the preceding table
- Conversions in either direction between **Boolean** and any numeric type
- Any numeric type to any enumerated type
- Conversions in either direction between a **Char()** array and a **String**
- Conversions in either direction between **String** and any numeric type, **Boolean**, or **Date**
- Conversions from a data type or object type to a type derived from it

Narrowing conversions do not always succeed, meaning that they might fail at run time. An error occurs if the destination data type cannot receive the value being converted. For example, a numeric conversion can result in an overflow. The compiler usually does not allow narrowing conversions to be performed implicitly.

You use a narrowing conversion when you know the source value can be converted to the destination data type without error. For example, if you have a **String** that you know contains either "True" or "False", you can use the **CBool** keyword to convert it to **Boolean**.

Implicit and Explicit Conversions | Value Changes During Conversions | Conversions Between Strings and Other Types | Typeless Programming | Data Type Summary | Type Conversion Functions | Boolean Data Type | Byte Data Type | Char Data Type | Date Data Type | Decimal Data Type | Double Data Type | Integer Data Type | Long Data Type | Object Data Type | Short Data Type | Single Data Type | String Data Type

Implicit and Explicit Conversions

An *implicit* conversion does not require any special syntax in the source code. In the following example, Visual Basic .NET implicitly converts the value of `K` to single-precision floating point before assigning it to `Q`.

```
Dim K As Integer
Dim Q As Double
' ...
K = 432   ' Integer widens to Double, so Option Strict can be On.
Q = K
```

An *explicit* conversion uses a type conversion keyword. Visual Basic .NET provides several such keywords, which coerce an expression in parentheses to the desired data type. These keywords act like functions, but the compiler generates the code inline, so execution is slightly faster than with a function call.

In the following extension of the preceding example, the **CInt** keyword converts the value of `Q` back to an integer before it is assigned to `K`:

```
Q = Math.Sqrt(Q)   ' Q had been assigned the value 432 from K.
K = CInt(Q)   ' K now has the value 21 (rounded square root of 432).
```

The following table shows the available conversion keywords.

Type conversion keyword	Converts an expression to data type	Allowable data types of expression to be converted
CBool	**Boolean**	Any numeric type (including **Byte** and enumerated types), **String**, **Object**
CByte	**Byte**	Any numeric type, any enumerated type, **Boolean**, **String**, **Object**
CChar	**Char**	**String**, **Object**
CDate	**Date**	**String**, **Object**
CDbl	**Double**	Any numeric type (including **Byte** and enumerated types), **Boolean**, **String**, **Object**
CDec	**Decimal**	Any numeric type (including **Byte** and enumerated types), **Boolean**, **String**, **Object**
CInt	**Integer**	Any numeric type (including **Byte** and enumerated types), **Boolean**, **String**, **Object**
CLng	**Long**	Any numeric type (including **Byte** and enumerated types), **Boolean**, **String**, **Object**
CObj	**Object**	Any type
CShort	**Short**	Any numeric type (including **Byte** and enumerated types), **Boolean**, **String**, **Object**
CSng	**Single**	Any numeric type (including **Byte** and enumerated types), **Boolean**, **String**, **Object**
CStr	**String**	Any numeric type (including **Byte**), **Boolean**, **Char**, **Char()** array, **Date**, **Object**
CType	Type specified following the comma (**,**)	When converting to an elementary type (including an array of an elementary type), the same types as allowed for the corresponding conversion keyword When converting to a composite type, the interfaces it implements and the classes from which it inherits

The CType Keyword

The **CType** keyword operates on two arguments. The first is the expression to be converted, and the second is the destination data type or object class. The following example demonstrates the use of **CType**.

```
K = CType(Q, Integer)  ' Uses CType keyword instead of CInt.
F = CType(W, Label)    ' Coerces W to the specific object class Label.
```

You can use **CType** to convert values to composite data types as well as to elementary types. You can also use it to coerce an object class to the type of one of its interfaces, as in the following example:

```
' Assume class CZone implements interface IZone.
Dim H As Object
Dim CZ As CZone   ' Cannot use a type as first argument of CType.
H = CType(CZ, IZone)   ' Coerces CZone object to its interface IZone.
```

CType can also convert array types, as in the following example:

```
Dim V() As ClassV   ' Array of ClassV objects.
Dim ObArray() As Object   ' Array of objects to be assigned.
' Some object array is assigned to ObArray.
If TypeOf ObArray Is ClassV()   ' Check for run-time type compatibility.
   V = CType(ObArray, ClassV())   ' ObArray can be converted to ClassV.
End If
```

> **Note** Values used with a conversion keyword must be valid for the destination data type, or an error occurs. For example, if you attempt to convert a **Long** to an **Integer**, the value of the **Long** must be within the valid range for the **Integer** data type.
>
> **Caution** Specifying **CType** to convert from one class type to another fails at run time if there is no inheritance relationship between the two types.

Performing an explicit conversion is also known as *casting* an expression to a given data type or object class.

Value Changes During Conversions

A conversion from a value type stores a copy of the source value in the destination of the conversion. However, this copy is not an exact image of the source value. The destination data type stores values differently, and even the value being represented might change, depending on the kind of conversion being performed.

Changes During Widening and Narrowing Conversions

Narrowing conversions change the destination copy of the source value with potential information loss. For example, a fractional value is rounded when converted to an integral type, and a numeric type being converted to **Boolean** is reduced to either **True** or **False**.

Widening conversions preserve the value but can change its representation. This happens if you convert from an integral type to **Decimal**, or from **Char** to **String**.

The original source value is not changed as a result of a conversion.

Changes During Reference Type Conversions

A conversion from a reference type copies only the pointer to the value. The value itself is neither copied nor changed in any way. The only thing that changes is the data type of the variable holding the pointer. In the following example, the data type is converted from the derived class to its base class, but the object now pointed to by both variables is unchanged:

```
' Assume class CSquare inherits from class CShape.
Dim Shape As CShape
Dim Square As CSquare = New CSquare
' ...
Shape = Square   ' Widening conversion from derived class to base class.
```

Widening and Narrowing Conversions | Implicit and Explicit Conversions | Conversions Between Strings and Other Types | Typeless Programming

Conversions Between Strings and Other Types

You can convert a numeric, **Boolean**, or date/time value to a **String**. You can also convert in the reverse direction — from a string value to numeric, **Boolean**, or **Date** — provided the contents of the string can be interpreted as a valid value of the destination data type. If they cannot, a run-time error occurs.

The conversions for all these assignments, in either direction, are narrowing conversions. You should use the type conversion keywords (**CStr**, **CShort**, **CInt**, **CLng**, **CDec**, **CSng**, **CDbl**, **CBool**, **CDate**, and **CType**). The **Format** and **Val** functions give you additional control over conversions between strings and numbers.

Conversion of Numbers to Strings

You can use the **Format** function to convert a number to a formatted string, which can include not only the appropriate digits but also formatting symbols such as a currency sign (such as **$**), thousands separators or *digit grouping symbols* (such as **,**), and a decimal separator (such as **.**). **Format** automatically uses the appropriate symbols according to the **Regional Options** settings specified in the Windows **Control Panel**.

Note that the concatenation (**&**) operator can convert a number to a string implicitly, as shown in the following example:

```
Str = "The total count is " & Count    ' Count is converted to String.
```

Conversion of Strings to Numbers

You can use the **Val** function to explicitly convert the digits in a string to a number. **Val** reads the string until it encounters a character other than a digit, space, tab, line feed, or period. The sequences "&O" and "&H" alter the base of the number system and terminate the scanning. Until it stops reading, **Val** converts all appropriate characters to a numeric value. For example, the following statement returns the value 141.8:

```
Val(" 14 1.8 miles")
```

When Visual Basic converts a string to a numeric value, it uses the **Regional Options** settings specified in the Windows **Control Panel** to interpret the thousands separator, decimal separator, and currency symbol. This means that a conversion might succeed under one setting but not another. For example, `"$14.20"` is acceptable in the English (United States) locale but not in any French locale.

Array Conversions

You can convert an array type to a different array type provided the following conditions are met:

- The ranks of the two arrays must be the same; that is, they must have the same number of dimensions. However, the lengths of the respective dimensions do not need to be the same.
- The data types of the elements of both arrays must be reference types. You cannot convert an **Integer** array to a **Long** array, or even to an **Object** array, because at least one value type is involved.
- A conversion, either widening or narrowing, must be possible between the element types of the two arrays. An example that fails this requirement is an attempted conversion between a **String** array and an array of a class derived from **System.Enum**. These two types have nothing in common, and no conversion of any kind exists between them.

A conversion of one array type to another is widening or narrowing depending on whether the conversion of the respective elements is widening or narrowing.

Conversion to an Object Array

When you declare an **Object** array without initializing it, its element type is **Object** as long as it remains uninitialized. When you set it to an array of a specific class, it takes on the type of that class. However, its underlying type is still **Object**, and you can subsequently set it to another array of an unrelated class. Since all classes derive from **Object**, you can change the array's element type from any class to any other class. In the following example, no conversion exists between types `Student` and **String**, but both derive from **Object**, so all assignments are valid:

```
' Assume Student has already been defined as a class.
Dim MyArray() As Object   ' MyArray is an Object array at this point.
Dim Names() As String = New String(3) {"Name0", "Name1", "Name2", "Name3"}
' ...
MyArray = New Student(3) {}   ' MyArray is now of type Student.
MyArray = Names   ' MyArray is now of type String.
```

If you originally declare an array with a specific class, its underlying element type is that class. If you subsequently set it to an array of another class, there must be a conversion between the two classes. In the following example, `Students` is a `Student` array. Since no conversion exists between **String** and `Student`, the last statement fails:

```
Dim Students() As Student   ' Students is a Student array at this point.
Dim Names() As String = New String(3) {"Name0", "Name1", "Name2", "Name3"}
' ...
Students = New Student(3) {}   ' Initialize to elements of type Student.
Students = Names   ' Fails at compile time -- no conversion exists.
```

Structures: Your Own Data Types

You can combine data items of different types to create a *structure*. A structure associates one or more *members* with each other and with the structure itself. When you declare a structure, it becomes a composite data type, and you can declare variables of that type.

A structure is a generalization of the user-defined type (UDT) supported by previous versions of Visual Basic. In addition to fields, structures can expose properties, methods, and events. A structure can implement one or more interfaces, and you can declare individual accessibility for each field.

Structures are useful when you want a single variable to hold several related pieces of information. For example, you might want to keep an employee's name, telephone extension, and salary together. You could use several variables for this information, or you could define a structure and use it for a single employee variable. The advantage of the structure becomes apparent when you have many employees and therefore many instances of the variable.

In This Section

Structure Declaration

Data Type Summary
Lists the elementary data types supplied by Visual Basic .NET.

Structure Declaration

You begin a structure declaration with the **Structure** statement, and you end it with the **End Structure** statement. Between these two statements you must declare at least one member. The members can be of any data type, but you must include at least one nonshared variable or an event.

If you want to keep an employee's name, telephone extension, and salary together in a single variable, you can declare a structure for this information as follows:

```
Private Structure Employee
   Public GivenName As String   ' This employee's given name.
   Public FamilyName As String   ' This employee's family name.
   Public Extension As Long   ' This employee's telephone extension.
   Private Salary As Decimal   ' This employee's annual salary.
   Public Sub GiveRaise(Raise As Double)   ' Raise this employee's salary.
      Salary *= Raise
   End Sub
   Public Event ReviewTime()   ' This employee must be reviewed.
End Structure
```

If you declare a structure as **Private**, as in the preceding example, it is inaccessible from outside an object created from the class defining the structure. The `Salary` field in the preceding example is also **Private**, which means it is inaccessible outside the structure, even from a class that can access the structure. However, the `GiveRaise()` procedure is **Public**, so it can be called from outside.

You can also define **Function** procedures, properties, and events in a structure. You can define one property as the default property, provided it takes at least one argument. You can handle an event with a **Shared Sub** procedure.

You can specify the accessibility of a structure using the **Public**, **Protected**, **Friend**, or **Private** keyword, or you can let it default to **Public**. You must declare every member and specify an accessibility for it. If you use the **Dim** statement without any keywords, the accessibility defaults to **Public**.

> **Note** You cannot initialize any of the structure members in the structure declaration. When you declare a variable to be of a structure type, you assign values to the members by accessing them through the variable.

See Also

Structure Statement | User-Defined Data Type

Structure Variables

Once you have created a structure, you can declare procedure-level and module-level variables as that type. For example, you can create a structure that records information about a computer system, as in the following code:

```
Public Structure SystemInfo
   Public CPU As String
   Public Memory As Long
   Public PurchaseDate As Date
End Structure
```

You can now declare variables of that type, as follows.

```
Dim MySystem, YourSystem As SystemInfo
```

> **Note** In classes and modules, structures declared using the **Dim** statement default to public access. If you intend a structure to be private, make sure you declare it using the **Private** keyword.

Access to Structure Values

To assign and retrieve values from the elements of a structure variable, you use the same syntax as you use to set and get properties on an object. For example, using the variables previously declared as `SystemInfo`, you can access their elements as follows.

```
MySystem.CPU = "486"
Dim TooOld As Boolean
If YourSystem.PurchaseDate < #1/1/1992# Then TooOld = True
```

You can also assign one variable to another if both are of the same structure type. This copies all the elements of one structure to the corresponding elements in the other, as in the following example:

```
YourSystem = MySystem
```

If a structure element is a reference type, such as a **String**, **Object**, or array, the pointer to the data is copied. If `SystemInfo` had included an object variable, then the preceding example would have copied the pointer from `MySystem` to `YourSystem`, and a change to the object's data through one structure would be in effect when accessed through the other structure.

Structures: Your Own Data Types | Structures and Other Programming Elements | Structures and Classes

Structure Statement

Structures and Other Programming Elements

You can use structures in conjunction with arrays, objects, and procedures, as well as with each other. The interactions use the same syntax as these elements use individually.

> **Note** You cannot initialize any of the structure members in the structure declaration. You can assign values only to members of a variable that has been declared to be of a structure type.

Structures and Arrays

A structure can contain an array as one of its elements, as shown in this example:

```
Public Structure SystemInfo
   Public CPU As String
   Public Memory As Long
   Public DiskDrives() As String   ' Array of changeable size.
   Public PurchaseDate As Date
End Structure
```

You access the values of an array within a structure the same way you access a property on an object, as shown in this example:

```
Dim MySystem As SystemInfo
ReDim MySystem.DiskDrives(3)
MySystem.DiskDrives(0) = "1.44 MB"
```

You can also declare an array of structures, as shown in this example:

```
Dim AllSystems(100) As SystemInfo
```

You follow the same rules to access the components of this data architecture, as shown in this example:

```
ReDim AllSystems(5).DiskDrives(3)
AllSystems(5).CPU = "386SX"
AllSystems(5).DiskDrives(2) = "100M SCSI"
```

Structures and Objects

A structure can contain an object as one of its elements, as shown in the following example:

```
Protected Structure UserInput
   Public UserName As String
   Public InputForm As System.Windows.Forms.Form
   Public UserFileNumber As Integer
End Structure
```

You should use a specific object class in such a declaration, rather than **Object**.

Structures and Procedures

You can pass a structure as a procedure argument, as shown in this example:

```
Public CurrentCPUName As String = "700MHz Pentium compatible"
Public CurrentMemorySize As Long = 256
' ...
Public Sub FillSystem(ByRef SomeSystem As SystemInfo)
   SomeSystem.CPU = CurrentCPUName
   SomeSystem.Memory = CurrentMemorySize
   SomeSystem.PurchaseDate = Now
End Sub
```

The preceding example passes the structure by reference, which allows the procedure to modify its elements so that the changes take effect in the calling code. If you want to protect a structure against such modification, pass it by value.

You can also return a structure from a function procedure, as shown in this example:

```
Dim AllSystems(100) As SystemInfo
' ...
Function FindByDate(ByVal SearchDate As Date) As SystemInfo
   Dim I As Integer
   For I = 1 To 100
      If AllSystems(I).PurchaseDate = SearchDate Then Return AllSystems(I)
   Next I
   ' Process error: system with desired purchase date not found.
End Function
```

Structures Within Structures

Structures can contain other structures, as shown in the following example:

```
Public Structure DriveInfo
   Public Type As String
   Public Size As Long
End Structure
' ...
Public Structure SystemInfo
   Public CPU As String
   Public Memory As Long
   Public DiskDrives() As DriveInfo   ' Array of changeable size.
   Public PurchaseDate As Date
End Structure
' ...
Dim AllSystems(100) As SystemInfo
ReDim AllSystems(1).DiskDrives(3)
AllSystems(1).DiskDrives(0).Type = "Floppy"
```

You can also use this technique to encapsulate a structure defined in one module within a structure defined in a different module.

Structures can contain other structures to an arbitrary depth.

Structures and Classes

Visual Basic .NET unifies the syntax for structures and classes, with the result that both entities support most of the same features. However, there are also important differences between structures and classes.

Similarities

Structures and classes are similar in the following respects:

- Both are *container* types, meaning that they contain other types as members.
- Both have members, which can include constructors, methods, properties, fields, constants, enumerations, events, and event handlers.
- Members of both can have individualized accessibilities. For example, one member can be declared **Public** and another **Private**.
- Both can implement interfaces.
- Both can have shared constructors, with or without parameters.
- Both can expose a default property, provided that property takes at least one argument.
- Both can declare and raise events, and both can declare delegates.

Differences

Structures and classes differ in the following particulars:

- Structures are value types; classes are reference types.
- Structures use stack allocation; classes use heap allocation.
- All structure members are **Public** by default; class variables and constants are **Private** by default, while other class members are **Public** by default. This behavior for class members provides compatibility with the Visual Basic 6.0 system of defaults.
- A structure must have at least one nonshared variable or event member; a class can be completely empty.
- Structure members cannot be declared as **Protected**; class members can.
- A structure procedure can handle events only if it is a **Shared Sub** procedure, and only by means of the **AddHandler** statement; any class procedure can handle events, using either the **Handles** keyword or the **AddHandler** statement.
- Structure variable declarations cannot specify initializers, the **New** keyword, or initial sizes for arrays; class variable declarations can.
- Structures implicitly inherit from the **ValueType** class and cannot inherit from any other type; classes can inherit from any class or classes other than **ValueType**.
- Structures are not inheritable; classes are.
- Structures are never terminated, so the common language runtime (CLR) never calls the **Finalize** method on any structure; classes are terminated by the garbage collector, which calls **Finalize** on a class when it detects there are no active references remaining.
- A structure does not require a constructor; a class does.
- Structures can have nonshared constructors only if they take parameters; classes can have them with or without parameters.

Every structure has an implicit public constructor without parameters. This constructor initializes all the structure's data members to their default values. You cannot redefine this behavior.

Instances and Variables

Because structures are value types, each structure variable is permanently bound to an individual structure instance. But classes are reference types, and an object variable can refer to various class instances. This distinction affects your usage of structures and classes in the following ways:

- A structure variable implicitly includes an initialization of the members using the structure's parameterless constructor. Therefore, `Dim S As Struct1` is equivalent to `Dim S As Struct1 = New Struct1()`.
- When you assign one structure variable to another, or pass a structure instance to a procedure argument, the current values of all the variable members are copied to the new structure. When you assign one object variable to another, or pass an object variable to a procedure, only the reference pointer is copied.

- You can assign the value **Nothing** to a structure variable, but the instance continues to be associated with the variable. You can still call its methods and access its data members, although variable members are reinitialized by the assignment. In contrast, if you set an object variable to **Nothing**, you dissociate it from any class instance, and you cannot access any members through the variable until you assign another instance to it.
- An object variable can have different class instances assigned to it at different times, and several object variables can refer to the same class instance at the same time. Changes you make to the values of class members affect those members when accessed through another variable pointing to the same instance. Structure members, however, are isolated within their own instance. Changes to their values are not reflected in any other structure variables, even in other instances of the same **Structure** declaration.
- Equality testing of two structures must be performed with a member-by-member test. Two object variables can be compared using the **Equals** method. **Equals** indicates whether the two variables point to the same instance.

Typeless Programming

By default, the Visual Basic compiler enforces two rules that affect your source code:

- Every local variable must appear in a declaration statement before being used in any other kind of statement.
- Every narrowing type conversion must be specified with a type conversion keyword.

You can change either or both of these rules by resetting corresponding compiler options. If you change the type conversion rule, the compiler operates under *permissive type semantics*, which allows you to make narrowing conversions without conversion keywords.

If you change the variable declaration rule, you can then use *typeless programming*, which permits you to refer to variables without first declaring them. Typeless programming is not usually recommended because it can lead to subtle execution errors involving data types. However, you might find it useful in some circumstances, such as porting an old application that did not declare variables.

Implicit and Explicit Declaration

By default, the Visual Basic compiler enforces *explicit declaration*, which requires that you declare every variable before you use it. You can remove this requirement and permit *implicit declaration*. Visual Basic provides a switch that controls explicit declaration. If you turn this switch off, you can use variables without declaring them.

You can set the explicit declaration switch on or off in any of the following ways:

- Setting the appropriate project property in the **Properties** window of the integrated development environment (IDE)
- Specifying the **/optionexplicit** command-line compiler option
- Including the **Option Explicit** statement at the beginning your code

If you use the **Option Explicit** statement, that setting overrides both the project property and compiler option settings, but only for the source code file in which it appears.

Setting **Option Explicit On** has the advantage of forcing type inference to be made at compile time instead of run time. This improves performance.

Implicit Declaration

If you turn explicit declaration off, you can implicitly declare a variable by simply using it in your code. All implicitly declared variables are given the data type **Object**. However, your application is more efficient if you declare all your variables explicitly and with a specific data type. This reduces the incidence of naming-conflict errors and spelling mistakes. It also allows the compiler to detect potential run-time errors such as assigning an **Integer** to a **Short**.

You can write a function in which you do not declare a local variable, as in the following example:

```
Function SafeSqrt(Num)
   TempVal = Math.Abs(Num)   ' Make sure value is positive for square root.
   Return Math.Sqrt(TempVal)
End Function
```

Visual Basic automatically creates `TempVal` as a local variable, which you can use as if you had explicitly declared it. While this is convenient, it can lead to subtle errors in your code if you misspell a variable name. Suppose you had written the function in the preceding example as follows:

```
Function SafeSqrt(Num)
   TempVal = Math.Abs(Num)   ' Make sure value is positive for square root.
   Return Math.Sqrt(TemVal)
End Function
```

At first glance, this code looks the same. But because the `TempVal` variable is misspelled as the argument to `Sqrt`, the compiler creates an additional local variable called `TemVal`, which is never assigned a value, and your function always returns zero.

When Visual Basic encounters a new name, it cannot determine whether you meant to implicitly declare a new variable or you just misspelled an existing one, so it creates a new variable with that name. Alternatively, the compiler might already have that name defined, and your code would use that definition unintentionally.

You can avoid problems with misnamed variables by using explicit declaration.

Explicit Declaration

Had explicit declaration been in effect for the module containing the `SafeSqrt` function in the preceding example, Visual Basic would have recognized `TempVal` and `TemVal` as undeclared variables and generated errors for both of them. As a result, you would then explicitly declare `TempVal`, as follows:

```
Function SafeSqrt(Num As Single) As Single
   Dim TempVal As Single = Math.Abs(Num)
   Return Math.Sqrt(TemVal)
End Function
```

With this revised code, you would understand the problem immediately because Visual Basic would display an error message for the incorrectly spelled `TemVal`. Because explicit declaration helps you catch these kinds of errors, it is recommended that you use it

with all your code.

> **Note** The **Option Explicit** statement operates on a file-by-file basis. It must be at the beginning of every source code file in which you want to control the enforcement of explicit variable declaration.

Variables | Lifetime | Visual Basic Naming Conventions | Data Type Summary | Option Explicit Statement | /optionexplicit | Setting Visual Basic Project Properties

Type Checking

When converting between data types, the Visual Basic compiler can operate under strict or permissive type semantics. If *strict type semantics* are in effect, only widening conversions are permitted implicitly, and narrowing conversions must be explicit. Under *permissive type semantics*, all widening and narrowing conversions can be done implicitly. Type semantics apply to conversions between all data types, including object types.

Visual Basic .NET provides a switch that controls type checking. By default, this switch is on, and the compiler enforces strict type semantics. If you turn the switch off, you can perform narrowing conversions without using conversion keywords.

You can set the type checking switch on or off in any of the following ways:

- Setting the appropriate project property in the **Properties** window of the integrated development environment (IDE)
- Specifying the **/optionstrict** command-line compiler option
- Including the **Option Strict** statement at the beginning your code

If you use the **Option Strict** statement, that setting overrides both the project property and compiler option settings, but only for the source code file in which it appears.

Setting **Option Strict On** has the advantage of forcing early binding. This improves performance.

See Also

Widening and Narrowing Conversions | Implicit and Explicit Conversions | Option Strict Statement | /optionstrict | Setting Visual Basic Project Properties

Object as the Universal Data Type

The **Object** data type is the root type in Visual Basic .NET. This means that all other data types and object types are derived from it, either directly or ultimately. It also means that any other data type, whether elementary or composite, can be converted to **Object**.

If you have turned **Option Strict** off, you can use **Object** as the universal data type. This is called *loose typing*. The following example illustrates this flexibility:

```
Dim V As Object
V = "17"   ' V contains the 2-character string "17".
V = V - 15   ' V now contains the integer value 2.
V = "H" & V   ' V now contains the 2-character string "H2".
```

While you can perform operations on **Object** variables without much concern for the kind of data they contain, there are some traps you must avoid.

- If you perform arithmetic operations or functions on an **Object**, it must hold numerical data.
- If you are concatenating strings, use the **&** operator instead of the **+** operator.

Changing Data Type

Although an **Object** variable can accept data of any type, it cannot be redimensioned to a different data type. However, you can redimension an **Object** variable to an array of **Object** variables. The following example illustrates both valid and invalid uses of the **ReDim** statement:

```
Dim SomeObj As Object   ' Initial declaration as a single Object.
ReDim SomeObj(8)   ' Valid reallocation for Object only.
ReDim SomeObj(8) As Double   ' INVALID change of data type.
```

The first **ReDim** statement changes `SomeObj` to an array of type **Object**. This is valid only with the **Object** data type. The second **ReDim** statement is invalid because it involves a different data type. You can achieve the desired effect with the following code:

```
Dim SomeArray(8) As Double  ' First allocate a separate array.
SomeObj = SomeArray         ' Assign new array to Object variable.
```

Object as an Alternative to a Structure

Because the **Object** data type can store many different types of data, you can use an **Object** array in many situations where you might expect to use a structure. An **Object** array is somewhat more flexible than a structure, because you can change the type of data you store in each element at any time, and you can make the array dynamic so you can change its size as necessary. However, an **Object** array uses more memory than an equivalent structure.

Efficient Use of Data Types

Undeclared variables and variables declared without a data type are given the **Object** data type. This makes it easy to write programs quickly, but it can cause them to execute more slowly.

Specifying data types for all your variables is known as *strong typing*. Using strong typing has several advantages:

- It enables IntelliSense™ support for your variables. This allows you to see their properties and other members as you type in the code.
- It allows the compiler to perform type checking. This catches statements that can fail at run time due to errors such as overflow. It also catches calls to methods on objects that do not support them.
- It results in faster execution of your code.

For variables that never contain fractions, the integral data types are more efficient than the nonintegral types. In Visual Basic .NET, **Integer** is the most efficient numeric type.

Use the **Dim** statement to declare a variable of a specific type. You can simultaneously specify its accessibility by using the **Public**, **Protected**, **Friend**, or **Private** keyword, as in the following example:

```
Private X As Double   ' X is a double-precision floating point.
Protected S As String   ' S is a character string.
```

Character Conversion

The **AscW** and **ChrW** functions operate in Unicode. You should use them in preference to **Asc** and **Chr**, which must translate into and out of Unicode.

Data Types | Data Type Declaration | Numeric Data Types | Variable Declaration | Asc, AscW Functions | Chr, ChrW Functions

Variables

You often need to store values temporarily when performing calculations with Visual Basic. For example, you might want to calculate several values, compare them, and perform different operations on them, depending on the result of the comparison. You need to retain the values if you want to compare them, but you don't need to store them in a property.

Visual Basic, like most programming languages, uses variables for storing values. A *variable* has a name (the word you use to refer to the value the variable contains) and a data type (which determines the kind of data the variable can store). A variable can represent an array if it needs to store an indexed set of closely related data items.

You use assignment statements to perform calculations and assign the result to a variable, as shown in the following code:

```
ApplesSold = 10              ' The value 10 is assigned to the variable.
ApplesSold = ApplesSold + 1  ' The variable is incremented.
```

> **Note** The equal sign (**=**) in this example is an assignment operator, not an equality operator. The value is being assigned to the variable `ApplesSold`.

Declared Elements
Discusses programming elements that are defined in declaration statements.

Variable Declaration

You declare a variable to specify its name and characteristics. The declaration statement for variables is the **Dim** statement. Its location and contents determine the variable's characteristics.

Declaration Levels

A *local variable* is one that is declared within a procedure. A *module variable* is declared at module level, inside the module but not within any procedure internal to that module.

In a class or structure, the category of a nonlocal variable depends on whether or not it is shared. If it is declared with the **Shared** keyword, it is a *shared variable*, and it exists in a single copy shared among all instances of the class or structure. Otherwise it is an *instance variable*, and a separate copy of it is created for each instance of the class or structure. A given copy of an instance variable is available only to the instance for which it was created.

Declaring Data Type

The **As** clause in the declaration statement allows you to define the data type or object type of the variable you are declaring. You can specify any of the following types for a variable:

- An elementary data type, such as **Boolean**, **Long**, or **Decimal**
- A composite data type, such as an array or structure
- An object type, or class, from Visual Basic or another application, such as **Label** or **TextBox**

You can declare several variables in one statement without having to repeat the data type. In the following statements, the variables `I`, `J`, and `K` are declared as type **Integer**, `L` and `M` as **Long**, and `X` and `Y` as **Single**:

```
Dim I, J, K As Integer            ' All three are Integer variables.
Dim L, M As Long, X, Y As Single  ' L and M are Long, X and Y are Single.
```

For more information on data types, see Data Types. For more information on objects, see Object-Oriented Programming in Visual Basic and Programming with Components.

Declaring Lifetime

The *lifetime* of a variable is the period of time during which it is available for use. A local variable declared with a **Dim** statement exists only as long as its procedure is executing. When the procedure terminates, all its local variables disappear and their values are lost. However, if you declare a local variable using the **Static** keyword, it continues to exist and preserve its value even when the procedure ends.

Module, shared, and instance variables retain their values as long as your application continues to run.

For more information on lifetime, see Lifetime.

Declaring Scope

The *scope* of a variable is the set of all code that can refer to it without qualifying its name. A variable's scope is determined by where the variable is declared. Code located in a given region can use the variables defined in that region without having to qualify their names. When declaring scope, the following rules apply:

- The scope of a module variable is the entire namespace in which the module is defined.
- The scope of a shared or instance variable is the structure or class in which it is declared.
- The scope of a local variable is the procedure in which it is declared.
- However, if you declare a local variable within a block, its scope is that block only. A block is a set of statements terminated by an **End**, **Else**, **Loop**, or **Next** statement; for example, a **For...Next** or **If...Then...Else...End If** construction.

For more information on scope, see Scope.

Declaring Accessibility

A variable's accessibility is determined by which keyword or keywords — **Dim**, **Public**, **Protected**, **Friend**, **Protected Friend**, or **Private** — you use in the declaration statement. You can declare a module, structure, class, or instance variable with any of these

keywords. Within a procedure, only the **Dim** keyword is allowed, and the accessibility is always private.

For more information on accessibility, see Accessibility.

Choice of Variable Scope

The *scope* of a variable is the set of all code that can refer to it without qualifying its name. A variable's scope is determined by where the variable is declared.

When considering scope, keep in mind that local variables are a good choice for any kind of temporary calculation. They consume memory only when their procedure is running, and their names are not susceptible to conflict. For example, you can create several different procedures containing a variable called `intTemp`. As long as each `intTemp` is declared as a local variable, each procedure recognizes only its own version of `intTemp`. Any one procedure can alter the value in its local `intTemp` without affecting `intTemp` variables in other procedures.

> **Note** Module, shared, instance, and static variables consume memory resources until your application stops running, so use them only when necessary.

In general, when declaring any variable or constant, it is good programming practice to make the scope as narrow as possible (block scope is the narrowest). This helps conserve memory and minimizes the chances of your code erroneously referring to the wrong variable. Similarly, you should declare a variable to be **Static** only when it is necessary to preserve its value between procedure calls.

Object Variables

In addition to storing values, a variable can refer to an object. You assign an object to a variable for the same reasons you assign any value to a variable:

- A variable name is often shorter and easier to remember than the full path of methods or properties necessary to access the object itself.
- Using a variable that refers to an object is more efficient than repeatedly accessing the object itself through the necessary methods or properties.
- You can change a variable to refer to other objects while your code is running.

You can use object variables to shorten the code you have to type. For example, you might have a code segment like the following:

```
' Assume Me is a valid Form, or replace Me with a valid Form.
Me.Activate()   ' Make this the active form.
Me.ActiveControl = Label1   ' Make some valid control the active control.
' ...
Me.ActiveForm.ActiveControl.Text = "Test"
Me.ActiveForm.ActiveControl.Location = New Point(100, 100)
Me.ActiveForm.ActiveControl.Show()
```

You can shorten this code, and speed up execution, if you use an object variable for the control. You should declare the object variable with the specific class that you intend to assign to it (`Control` in the following example). Once you assign an object to the variable, you can treat it exactly the same as you do the object to which it refers. You can set or return the properties of the object or use any of its methods, as shown in the following example:

```
Dim ctrlBal As Control  ' Must declare to be of class Control.
' ...
ctrlBal = Me.ActiveForm.ActiveControl
ctrlBal.Text = "Test"
ctrlBal.Location = New Point(100, 100)
ctrlBal.Show()
```

Variable Declaration
Describes how to specify variable names and characteristics, including which type of data the variable can contain.

Object Variable Declaration

You use a normal declaration statement to declare an object variable, but for the data type, you specify either **Object** or the *object class*. The object class is the specific class from which the object is to be instantiated. When you declare a variable with a specific object class, it can access all the methods and properties exposed by that class. If you declare the variable with **Object**, it can use only the members of the **Object** class, unless you turn off the type-checking switch (Option Strict Statement).

Use the following syntax to declare an object variable:

```
Dim variablename As [New] {objectclass | Object}
```

You can also use **Protected**, **Friend**, **Protected Friend**, **Private**, **Shared**, or **Static** for the declaration. The following declarations are valid:

```
Private ObjA As Object     ' Declare ObjA as generic Object data type.
Static ObjB As Label       ' Declare ObjB as Label class type.
Dim ObjC As System.Buffer  ' Declare ObjC as Buffer class type.
```

Sometimes the object class is not known until the procedure runs. In this case, you must declare the object variable with the **Object** data type. This creates a generic reference to any type of object. It also limits your code to the methods and properties of **System.Object** when **Option Strict** is turned on.

When you know the specific object class, you should declare the object variable to be of that class. In the preceding example declarations, if the application uses objects of class **Label**, you should specify **As Label** in the declarations for both `ObjA` and `ObjB`.

Declaring an object variable as a specific object class gives you several advantages:

- Automatic type checking
- Microsoft IntelliSense support in the Code editor
- Improved readability
- Fewer errors in your code
- Faster code execution

Access to Object Variable Members

When **Option Strict** is turned on, an object variable can access only the methods and properties of the class with which you declared it. The following example illustrates this:

```
' Option statements must precede all other source file lines.
Option Strict On
' Imports statement must precede all declarations in the source file.
Imports System.Windows.Forms
Dim P As Object
Dim Q As Label
P = New Label                ' Assign Label class to Object declaration.
Q = New Label                ' Assign Label class to Label declaration.
' ...
Dim J, K As Integer
J = P.Left                   ' Generates a compiler error.
K = Q.Left                   ' Returns left edge of label in pixels.
```

In this example, `P` can use only the members of the **Object** class itself, which do not include the `Left` property. On the other hand, `Q` was declared to be of type **Label**, so it can use all the methods and properties of the **Label** class in the **System.Windows.Forms** namespace.

Flexibility of Object Variables

When working with objects in an inheritance hierarchy, you have a choice of which class to use for declaring your object variables. In making this choice, you must balance flexibility of object assignment against access to a class's members. For example, consider the inheritance hierarchy that leads to the **Form** class:

Object Class

MarshalByRefObject
MarshalByRefComponent
Control Class
RichControl
ScrollableControl
ContainerControl
Form Class

Suppose your application defines a form called `Form2`, which inherits from class **Form**. You can declare an object variable that refers specifically to `Form2`, as follows:

```
Dim MyForm As New Form2    ' Can assign only Form2 objects to MyForm.
```

This limits the variable `MyForm` to objects of class `Form2`, but it also makes all the methods and properties of `Form2` available to `MyForm`, as well as all the members of all the classes from which `Form2` inherits.

You can make an object variable more general by declaring it to be of type **Form**, as follows:

```
Dim AnyForm As Form        ' Can assign any form, but no other control.
```

This allows you to assign any form in your application to `AnyForm`. However, although `AnyForm` can access all the members of class **Form**, it cannot use any of the additional methods or properties defined for specific forms such as `Form2`, unless you turn off **Option Strict**.

Object Variable Assignment

You use a normal assignment statement to assign an object to an object variable. You can assign an object expression or the **Nothing** keyword, as in the following code:

```
Dim MyObject, YourObject As Object
' ...
MyObject = YourObject  ' Assign an object reference.
MyObject = Nothing     ' Discontinue association with any object.
```

Nothing means there is no object currently assigned to the variable. When your code begins running, your object variables are initialized to **Nothing**, except for those whose declarations include assignment.

You can combine assignment with declaration by using the **New** keyword. The following declaration statements declare object variables and assign specific objects to them. The second statement uses one of the overloaded constructors of the **Version** class in the **System** namespace to initialize the object:

```
Dim MyURI As New System.Uri("http://www.microsoft.com")
Dim Major, Minor, Revision As Integer
Dim Ver As New System.Version(Major, Minor, Revision)
```

Setting an object variable to **Nothing** discontinues the association of the variable with any specific object. This prevents you from accidentally changing the object by changing the variable. It also allows you to test whether the object variable points to a valid object, as in the following example:

```
If Not MyObject Is Nothing Then
   ' MyObject refers to a valid object, so your code can use it.
   ' ...
End If
```

If the object your variable refers to is in another application, this test cannot determine whether that application has been closed.

Current Instance of an Object

The *current instance* of an object is the one in which the code is currently executing. Since all code executes inside a procedure, the current instance is the one in which the procedure was invoked.

The **Me** keyword acts as an object variable referring to the current instance. If a procedure is not shared, it can use the **Me** keyword to obtain a pointer to the current instance. Shared procedures cannot be associated with a single instance of an object.

Using **Me** is particularly useful for passing the current instance to a procedure in another module. For example, if you have a number of XML documents and wish to add some standard text to all of them, you could define the following procedure:

```
Sub AddStandardText(XmlDoc As System.Xml.XmlDocument)
   XmlDoc.CreateTextNode("This text goes into every XML document.")
End Sub
```

Every XML document object could then call the procedure and pass its current instance as an argument using the following statement:

```
AddStandardText(Me)
```

Object Variable Values

An object variable can refer to data of any type. The value you store in an object variable is kept elsewhere in memory, while the variable itself holds a pointer to the data.

Visual Basic supplies functions that return information about what an object variable refers to, as shown in the following table.

Function	Returns True if the Object variable refers to
IsArray	An array of values, rather than a single value
IsDate	A number or string that can be interpreted as a date and time valu e
IsNumeric	A number, or something that can be interpreted as a number

You can use these functions to avoid submitting an invalid value to an operation or a procedure.

You can also use the **TypeOf** operator to determine whether an object variable currently refers to a specific data type. The **TypeOf...Is** expression evaluates to **True** if the run-time type of the operand is derived from or implements the specified type. The following example uses **TypeOf** on object variables referring to value and reference types:

```
Dim Num As Object = 10          ' Value type (Integer).
Dim Frm As Object = New Form()  ' Reference type.
  ' ...
If TypeOf Num Is Long Then Debug.WriteLine("Num is Long")
If TypeOf Num Is Integer Then Debug.WriteLine("Num is Integer")
If TypeOf Num Is Short Then Debug.WriteLine("Num is Short")
If TypeOf Num Is Object Then Debug.WriteLine("Num is Object")
  ' ...
If TypeOf Frm Is Form Then Debug.WriteLine("Frm is Form")
If TypeOf Frm Is Label Then Debug.WriteLine("Frm is Label")
If TypeOf Frm Is Object Then Debug.WriteLine("Frm is Object")
```

The preceding example writes the following lines to the Debug window:

```
Num is Integer
Num is Object
Frm is Form
Frm is Object
```

The object variable `Num` refers to data of type **Integer**, and `Frm` refers to an object of class **Form**.

You can declare and use an array of **Object** variables. This is useful when you need to handle a variety of data types and object classes. All the elements in an array must have the same declared data type. Declaring this data type as **Object** allows you to store objects and class instances alongside other data types in the array.

Arrays

When you use arrays, you can refer to multiple variables by the same name, using a number called an *index* or *subscript* to distinguish them from one another. Arrays can shorten and simplify your code, allowing you to create loops that deal efficiently with any number of elements.

Arrays Overview

Arrays allow you to refer to a series of variables by the same name and to use a number, called an *index* or *subscript*, to tell them apart. This helps you create shorter and simpler code in many situations, because you can set up loops that deal efficiently with any number of elements by using the index number.

Array Dimensions

An array can have one dimension or more than one. The *dimensionality* or *rank* corresponds to the number of subscripts used to identify an individual element. You can specify up to 32 dimensions, although more than three is extremely rare.

Array Size

Every dimension of an array has a nonzero length. The elements of the array are contiguous along each dimension from subscript 0 through the highest subscript of that dimension. Because Visual Basic allocates space for an array element corresponding to each index number, you should avoid declaring any dimension of an array larger than necessary.

A *zero-length array* is an array with no elements. It is sometimes necessary to specify such an array, for example when using Windows Forms. To do this, you declare one of the array's dimensions to be –1. The array is then empty, but it still exists. Therefore, a variable pointing to the array is not equal to **Nothing**.

Arrays do not have fixed size in Visual Basic. You can change the size of an array after you have created it. The **ReDim** statement assigns a completely new array object to the specified array variable. Therefore, **ReDim** can change the length of each dimension.

Arrays as Objects

Arrays are objects in Visual Basic .NET, so every array type is an individual reference type. This has the following implications:

- An array variable holds a pointer to the data constituting the elements and the rank and length information.
- When you assign one array variable to another, only the pointer is copied.
- No two array variables are considered to be of the same data type unless they have the same rank and element data type.

Array Class

All arrays inherit from the **Array** class in the **System** namespace, and you can access the methods and properties of **System.Array** on any array. For example, the **Rank** property returns the array's rank, and the **Sort** method sorts its elements.

Array Element Type

An array declaration specifies a data type, and all its elements must be of that type. When the data type is **Object**, the individual elements can contain different kinds of data (objects, strings, numbers, and so on). You can declare an array of any of the fundamental data types, of a structure (described in Structures: Your Own Data Types), or of an object class (described in Object-Oriented Programming in Visual Basic).

You can also declare an array that contains other arrays as its elements. In this case, the constituent arrays must all have the same element data type, which you specify in the declaration. An array of arrays is called a *jagged array* because the constituent arrays do not have to have the same sizes.

> **Note** Jagged arrays are not compliant with the common language specification (CLS). This means you should not expose jagged arrays from any class you want CLS-compliant code to consume.

See Also

Array Usage | ReDim Statement | Declaring Array Variables | Advanced Features of Arrays | Arrays of Arrays | Collections as an Alternative to Arrays | Value Types and Reference Types | Parameter Arrays | Loop Structures | System Namespace | Array Class | Array.Rank Property | Array.Sort Method | Object Data Type

Array Usage

You can declare an array to work with a set of values of the same data type. An array is a single variable with many compartments to store values, while a scalar variable (that is, not an array) has only one storage compartment in which it can store only one value. You can refer to the array as a whole when you want to refer to all the values it holds, or you can refer to its individual elements one at a time.

For example, to store daily expenses for each day of the year, you can create one array with 366 elements, rather than declaring 366 variables. Each element in the array contains one value, which you access by specifying the element's index. The following example declares the array variable `CurExpense`, initializes it to have 366 elements, and then assigns an initial value of 20 to each element.

```
Sub FillArray()
   Dim CurExpense(365) As Decimal   ' Allocates (0) through (365).
   Dim I As Integer
   For I = 0 to 365
      CurExpense(I) = 20.00
   Next I
End Sub
```

You can mix data types in an array if it is declared of type **Object**. The following example stores employee information in the array variable `EmployeeData`.

```
Dim EmployeeData(3) As Object   ' Allocates (0) through (3).
EmployeeData(0) = "Ron Bendel"
EmployeeData(1) = "4242 Maple Blvd"
EmployeeData(2) = 48
EmployeeData(3) = "06-09-1953"
```

Multidimensional Arrays

In Visual Basic, you can declare arrays with up to 32 dimensions. For example, the following statement declares a two-dimensional array with 5 rows and 10 columns.

```
Dim Rectangle(4, 9) As Single   ' (0) through (4), (0) through (9).
```

The total number of elements is the product of the sizes of all the dimensions, in this case 50.

The rank of an array is held in its **Rank** property, and the length of each dimension is returned by the **GetLength** method. The lowest subscript value for a dimension is always 0, and the highest subscript value is returned by the **GetUpperBound** method for that dimension. Note that the argument you pass to **GetLength** and **GetUpperBound** (the dimension for which you want the length or the highest subscript) is 0-based.

> **Note** When you add dimensions to an array, the total storage needed by the array increases considerably, so use multidimensional and jagged arrays with care.

You can efficiently process a multidimensional array by using nested **For** loops. For example, the following statements initialize every element in `MatrixA` to a value between 0 and 99, based on its location in the array.

```
Dim I, J As Integer
Dim MaxDim0, MaxDim1 As Integer   ' Highest subscripts, not lengths.
Dim MatrixA(9, 9) As Double
MaxDim0 = MatrixA.GetUpperBound(0)   ' Maximum for first dimension.
MaxDim1 = MatrixA.GetUpperBound(1)   ' Maximum for second dimension.
For I = 0 To MaxDim0
   For J = 0 To MaxDim1
      MatrixA(I, J) = (I * 10) + J
   Next J
Next I
```

You can obtain the overall size of an array of any rank from its **Length** property. This represents the total number of elements

currently contained in the array, not the number of bytes they consume in storage. In the previous example, `MatrixA.Length` would return 100.

Declaring Array Variables

Array variables are declared the same way as other variables, using the **Dim** statement. You follow the variable name with one or more pairs of parentheses to indicate that it is an array rather than a *scalar* (a variable containing a single value).

To declare a single-dimensional array variable

- In your declaration, add one pair of parentheses after the variable name, as in the following example:

```
Dim MySingleArray() As Integer
```

To declare a multidimensional array variable

- In your declaration, add one pair of parentheses after the variable name and place commas inside the parentheses to separate the dimensions, as in the following example:

```
Dim My4DArray(,,,) As Short   ' Four-dimensional array.
```

To declare a jagged array variable

- In your declaration, add as many pairs of parentheses after the variable name as there are levels of nested arrays, as in the following example:

```
Dim MyJaggedArray()()() As Byte   ' Array of arrays of Byte arrays.
```

Initializing Arrays

You can initialize an array variable as part of its declaration. You can do one of the following in the declaration statement:

- Specify the initial length of one or more of the dimensions in the parentheses following the variable name, without assigning an array object to the variable.
- Assign an array object to the variable, using the **New** clause. When you use a **New** clause, you must follow it with braces (**{}**), even if they are empty.
- Assign an array object to the variable and supply initial lengths in the **New** clause.
- Assign an array object to the variable and supply initial element values in the **New** clause. You can supply both lengths and values in the same **New** clause.

If you specify dimension lengths in the parentheses following the variable name, you must use a subsequent assignment statement to assign an array object to the variable. The following sample declarations show valid and invalid syntax for a single-dimensional array variable:

```
Dim BA(2) As Byte   ' Currently contains Nothing (no object).
Dim BA(2) As Byte = New Byte()   ' INVALID (New after length specified).
Dim BA() As Byte = New Byte() {}   ' Empty Byte array object.
Dim BA() As Byte = New Byte()   ' INVALID (missing braces).
Dim BA() As Byte = New Byte(2)   ' INVALID (missing braces).
Dim BA() As Byte = New Byte() {0,1,2}   ' (0) through (2).
Dim BA() As Byte = New Byte(2) {0,1,2}   ' (0) through (2).
```

You can initialize a multidimensional array variable in a similar manner. The following sample declarations show a two-dimensional array variable being declared as an **Short** array with 2 rows and 2 columns.

```
Dim S2X2(1, 1) As Short   ' (0) through (1), (0) through (1).
Dim S2X2(1, 1) As Short = New Short(,)   ' INVALID (New after lengths).
Dim S2X2(,) As Short = New Short(,)   ' INVALID (missing braces).
Dim S2X2(,) As Short = New Short(1, 1)   ' INVALID (missing braces).
Dim S2X2(,) As Short = New Short(,) {}   ' Empty array object.
Dim S2X2(,) As Short = New Short(1, 1) {}   ' Elements have default value.
Dim S2X2(,) As Short = New Short(,) {{5, 6}, {7, 8}}   ' Four elements.
```

The first argument represents the rows; the second argument represents the columns. In the arrays in the preceding declarations, the index values for both the row and the column range from 0 through 1.

When you initialize a jagged array variable, you can specify the dimension lengths only for the top-level array. The following sample declarations show valid and invalid syntax for an array of arrays of **Byte** elements:

```
Dim JB(1)() As Byte   ' Array of two arrays of Byte elements.
Dim JB(1)(1) As Byte   ' INVALID (can only specify top-level size).
Dim JB(1)() As Byte = New Byte()()   ' INVALID (New after lengths).
Dim JB()() As Byte = {New Byte() {}, New Byte() {}}   ' Empty arrays.
Dim JB()() As Byte = {New Byte(1) {}, New Byte(1) {}}   ' Default values.
Dim JB()() As Byte = {New Byte() {5, 6}, New Byte() {7, 8}}
```

In the last of the preceding declarations, `JB` is initialized to two elements, `JB(0)` and `JB(1)`, each of which is initialized to a two-element **Byte** array, the first with element values 5 and 6 and the second with elements 7 and 8.

Array Size Limits

The length of every dimension of an array is limited to the maximum value of a **Long** data type, which is (2 ^ 64) - 1. The total size limit of an array varies, based on your operating system and how much memory is available. Using an array that exceeds the amount of RAM available on your system is slower because the data must be read from and written to disk.

> **Note** Because arrays are objects in Visual Basic .NET, it is important to distinguish between an array object and an array variable. An array object, once created, does not change its size or rank. An array variable, however, can have a succession of different arrays assigned to it during its lifetime, and these can be of different sizes and ranks.

Resizing Arrays

You can resize an array at any time by assigning a different array object to the same array variable, using either **ReDim** or a standard assignment statement. The new array object can have different dimensions, although it must retain the same rank. This helps you manage memory efficiently. For example, you can use a large array for a short time and then **ReDim** it to a smaller size. This frees up memory you no longer need.

When you **ReDim** an array, its existing values are normally lost. However, you can retain them by including the **Preserve** keyword in the **ReDim** statement. For example, the following statement allocates a new array, initializes its elements from the corresponding elements of the existing `MyArray`, and assigns the new array to `MyArray`.

```
ReDim Preserve MyArray(10, 20)
```

In a multidimensional array, you can change only the last dimension when you use **Preserve**. If you attempt to change any of the other dimensions, a run-time error occurs. If you do not know the current size of a dimension, you can use the **GetUpperBound** method, which returns the highest subscript value for the dimension you specify.

In the following example, the first line is valid, but the second line is not, because it attempts to change the first of two dimensions.

```
ReDim Preserve Matrix(Matrix.GetUpperBound(0), Matrix.GetUpperBound(1) + 10)
ReDim Preserve Matrix(Matrix.GetUpperBound(0) + 10, Matrix.GetUpperBound(1))
```

Advanced Features of Arrays

You can assign the contents of one array to another, create functions that accept and return arrays, and create properties that accept and return arrays. In many cases these techniques can improve the performance of your application.

Array Assignment

Since arrays are objects, they can be used in assignment statements like other object types. When assigning one array to another, the following rules apply:

- The rank (number of dimensions) of the destination array must be the same as that of the source array.
- Provided the ranks of the two arrays are equal, the dimensions do not need to be equal. The number of elements in a given dimension can change during assignment.
- Either both arrays must have reference type elements or both arrays must have value type elements.
- If both arrays have value type elements, the element data types must be exactly the same.
- If both arrays have reference type elements, there must be a widening conversion from the source element type to the destination element type.

The compiler reports an error if the above rules are violated, for example if a data type cannot be coerced or the ranks are unequal. You can add error handling to your code to make sure that the arrays are compatible before attempting an assignment.

Returning an Array from a Function

A function can return an array of values. For example, you might want to return a **Byte** array without having to perform conversions to and from a string. In the following example, the **Function** procedure `ArrayFunction` returns an array of bytes.

```
Dim B As Byte = CByte(54)   ' Seed value for ArrayFunction argument.
Dim I As Integer   ' Loop counter for displaying returned values.
Dim ReturnArray() As Byte   ' To be set from ArrayFunction return.
ReturnArray = ArrayFunction(B)
For I = 0 To ReturnArray.GetUpperBound(0)   ' Highest subscript.
   Debug.WriteLine("Byte " & I & ": " & ReturnArray(I))
Next I
' ...
Public Function ArrayFunction(ByVal B As Byte) As Byte()
   Dim X(2) As Byte   ' Allocates three elements.
   X(0) = B
   X(1) = B + B
   X(2) = B + CByte(200)
   Return X
End Function
```

After running the preceding example, `ReturnArray` points to a three-element array containing the element values assigned to the array `X` in `ArrayFunction`. In this example, `ReturnArray` must have the same element type as the function return because it is a value type (in this case **Byte**). If the element types of `ReturnArray` and `ArrayFunction` had been reference types, a widening conversion would have been acceptable.

Arrays of Arrays

Sometimes the data in your application is two-dimensional but not rectangular. As an example, you might have an array of months, each element of which is an array of days. Since different months have different numbers of days, the elements do not form a rectangular two-dimensional array. In such a case, you can use a jagged array instead of a multidimensional array, as the following example shows:

```
Dim Sales()() As Double = New Double(11)() {}   ' Assign top-level array.
Dim Month As Integer   ' Counter variable for month.
Dim Days As Integer   ' Days in given month for this year.
For Month = 0 To 11
   Days = DateTime.DaysInMonth(Year(Now), Month + 1)   ' Get number of days.
   Sales(Month) = New Double(Days - 1) {}   ' Assign array for this month.
Next Month
```

The declaration of `Sales` sets the array variable to a 12-element array, each element of which is an array of **Double** elements. The **For** loop then determines how many days are in each month this year (**Year(Now)**), and sets the corresponding element of `Sales` to a **Double** array of the appropriate length.

In the preceding example, the jagged array saves seven elements (six in a leap year) compared to a two-dimensional array. In a more extreme case the memory savings could be significant.

> **Note** Jagged arrays are not compliant with the common language specification (CLS). This means you should not expose jagged arrays from any class you want CLS-compliant code to consume.

Arrays of Objects

It is also possible to create an **Object** array and populate it with other arrays of different data types. The following code creates two arrays, one containing integers and the other strings. It then declares a third array of type **Object** and populates it with the integer and string arrays.

```
Dim I As Integer   ' Counter variable.
' Declare and populate an integer array.
Dim CountersA(4) As Integer   ' Allocates five elements.
For I = 0 To 4
   CountersA(I) = I
Next I
' Declare and populate a string array.
Dim CountersB(4) As String   ' Allocates five elements.
For I = 0 To 4
   CountersB(I) = "String number " & CStr(I)
Next I
' Declare a new two-element array and populate it with the other arrays.
Dim Counters(1) As Object'   ' Elements (0) and (1).
Counters(0) = CountersA
Counters(1) = CountersB
' Display a member of each array.
MsgBox(Counters(0)(2))   ' Displays "2".
MsgBox(Counters(1)(3))   ' Displays "String number 3".
```

In the preceding example, the calls to **MsgBox** use late binding on `Counters(0)` and `Counters(1)`. `Counters(0)(2)` is a specific object instance created on `Counters(0)`, and `Counters(1)(3)` is an instance on `Counters(1)`. The Visual Basic compiler allows late binding only when **Option Strict** is **Off**.

Collections as an Alternative to Arrays

Although collections are most often used for working with objects, you can use a collection to work with any data type. In some circumstances, it can be more efficient to store items in a collection than in an array.

You might want to use a collection if you are working with a small, dynamic set of items. The following code fragment shows how you might use a collection to save and display a list of URL addresses.

```
' Module-level collection declaration.
Public URLHistory As New Microsoft.VisualBasic.Collection
' ...
' Code for adding a specified URL address to the collection.
Private Sub SaveURLHistory(ByVal URLAddress As String)
   URLHistory.Add(URLAddress)
End Sub
' ...
' Code for displaying the list of URL addresses in the Immediate window.
Private Sub PrintURLHistory()
   Dim URLAddress As String
   For Each URLAddress In URLHistory
      Debug.WriteLine(URLAddress)
   Next URLAddress
End Sub
```

Objects

When you create an application in Visual Basic .NET, you constantly work with objects. You can use objects provided by Visual Basic — such as controls, forms, and data access objects or can also control objects from other applications within your Visual Basic application. You can even create your own objects, and define additional properties and methods for them. Objects act like prefabricated building blocks for programs — they let you to write a piece of code once and reuse it over and over.

The following topics discuss objects in detail:

In This Section

What Is an Object?

Covers object-oriented programming basics.

What Is an Object?

An object is a combination of code and data that can be treated as a unit. An object can be a piece of an application, like a control or a form. An entire application can also be an object.

Objects let you declare variables and procedures once and then reuse them whenever needed. For example, if you want to add a spell checker to an application you could define all the variables and support functions to provide spelling check functionality to your application. However, if you create your spell checker as a class, you can reuse it in other applications by adding a reference to the compiled assembly. Better yet, you may be able to save yourself some work by using a spell checker class that someone else has already developed.

Each object in Visual Basic .NET is defined by a class. Classes describe the fields, properties, methods, and events of an object. Objects are instances of classes; you can create as many objects you need once you have created a class.

To understand the relationship between an object and its class, think of cookie cutters and cookies. The cookie cutter is the class. It defines the characteristics of each cookie — for instance, size and shape. The class is used to create objects. The objects are the cookies.

Two examples of the relationship between classes and objects in Visual Basic .NET may make this clearer:

- The controls on the Toolbox in Visual Basic .NET represent classes. When you drag and drop a control from the toolbox onto a form, you are actually creating an object —an instance of a class.
- The form you work with at design time is a class. At run time, Visual Basic .NET creates an instance of the form's class.

Objects are created as identical copies of their class. Once they exist as individual objects, however, their properties can be changed. For example, if you add three check boxes to a form, each check box button object is an instance of the **CheckBox** class. The individual **CheckBox** objects share a common set of characteristics and capabilities (properties, fields, methods, and events), defined by the class. However, each has its own name, can be separately enabled and disabled, can be placed in a different location on the form.

Relation of Objects to Each Other

Objects can be related to each other in several ways. One such relationship is hierarchical. Classes that are derived from more fundamental classes are said to have a hierarchical relationship. Class hierarchies are useful when describing items that are a subtype of a more general class. Derived classes inherit members from the class they are based on, allowing you to add complexity as you progress in a class hierarchy.

Another way that objects are related is the object object-container relationship. Container objects encapsulate other objects. For example, an instance of class with a property that stores an object is a container object.

One type of object containment is represented by collections. Collections are like arrays of objects that can be enumerated. Visual Basic .NET supports a specific syntax in the form of **For Each...Next** syntax blocks that allow you to iterate the items of a collection. Additionally, collections often allow you to use a method named **Item** property to retrieve elements by their index or by associating them with a unique string. Collections are easier to use than arrays because they allow you to add or remove items without using indexes. Because of their ease of use, collections are often used to store forms and controls.

The Basics of Working with Objects

Almost everything you do in Visual Basic .NET involves objects. This topic shows you some ways that the elements of objects are used.

Member Access

You access the members of an object by specifying, in order, the name of the object, a period, and the name of the member you want to use. For example, if you have an object named Obj1 that has a property named Prop1 you could use the syntax `Obj1.Prop1` to access that property. In some cases you need to use several dots because objects can contain other objects. For example, you could use the syntax `Obj1.Prop1.X` if the property Prop1 is an object that contains a field named X.

Fields and Properties

Properties and fields represent information stored in an object. The values of fields and properties are retrieved and set with assignment statements the same way that variables are retrieved and set. The following example sets and retrieves the value of a field and a property.

```
Dim X As Integer = 8
Dim Obj1 As New Class1   ' Declares an instance of a class.
Obj1.Prop1 = X   ' Property assignment. Assigns the number 8 to Prop1.
X = Obj1.Prop1 + 1   ' Retrieval. The variable X contains the number 9.
Obj1.Field1 = X    ' Field assignment. Assigns the number 9 to Field1.
X = Obj1.Prop1 + 1   ' Retrieval. The variable X contains the number 10.
```

Methods

Methods are procedures defined within a class. Methods are used like subroutines or functions, but are accessed by way of the object to which they belong. The following code fragment calls a function and a subroutine declared in an object:

```
Dim Obj2 As New Class2   ' Declares an instance of a class
Dim Y As Integer
' Retrieves a value from a method declared as a function.
Y = Obj2.GetNumber
Obj2.StoreNumber(Y)   ' Calls a method declared as a subroutine.
```

Events

Events are notifications that cause a procedure to execute. Objects can both handle and generate events. Events are generated using the **RaiseEvent** statement and handled using either the **Handles** keyword or the **AddHandler** statement. The following example raises and handles an event declared using the **WithEvents** keyword:

```
' Declares a WithEvents variable in the declarations section.
   Dim WithEvents EClass As EventClass

   Class EventClass
      Public Event AnEvent()   ' Declares an event.

      Sub CauseEvent()
         RaiseEvent AnEvent()   'Raises an event.
      End Sub
   End Class

' Declares an event handler
   Sub EventHandler() Handles EClass.AnEvent
      MessageBox.Show("Received Event.")
   End Sub

' Test the class and the event handler.
   Sub TestEvents()
      EClass = New EventClass()   ' Creates an instance of the class.
      EClass.CauseEvent()   ' Calls a method that raises an event.
```

```
    End Sub
```

Objects, Properties, Methods, and Events

Objects, properties, methods, and events are the basic units of object-oriented programming. An object is an element of an application, representing an *instance* of a class. Properties, methods, and events are the building blocks of objects, and constitute their *members*.

Objects

An object represents an instance of a class such as **Form**, **Control**, or **Component**. In Visual Basic code, you must *instantiate* an object before you can apply one of the object's methods or change the value of one of its properties. Instantiation is the process by which an instance of a class is created and assigned to an object variable. An example is shown below:

```
Dim x As New MyClass()
```

In this example, the variable `x` is assigned to refer to a new instance of the class `MyClass`.

Properties

A property is an attribute of an object that defines one of the object's characteristics, such as size, color, or screen location, or an aspect of its behavior, such as whether it is enabled or visible. To change the characteristics of an object, you change the values of its corresponding properties.

To set the value of a property, affix the reference to an object with a period, the property name, an equal sign (=), and the new property value. For example, the following procedure changes the caption of a Visual Basic Windows Form by setting the **Text** property:

```
Public Sub ChangeName(newTitle)
   myForm.Text = newTitle
End Sub
```

You can't set some properties. The Help topic for each property indicates whether you can set that property (read/write), only read the property (read-only), or only write the property (write-only).

You can retrieve information about an object by returning the value of one of its properties. The following procedure uses a message box to display the title that appears at the top of the currently active form.

```
Public Sub GetFormName()
   Dim formName As String
   formName = myForm.Text
   MsgBox(formName)
End Sub
```

Methods

A method is an action that an object can perform. For example, **Add** is a method of the **ComboBox** object, because it adds a new entry to a combo box.

The following example demonstrates the **Start** method of a **Timer** component:

```
' Instantiates a Timer object.
Dim myTimer As New System.Windows.Forms.Timer()
' Invokes the Start method of myTimer.
MyTimer.Start
```

Events

An event is an action recognized by an object, such as clicking the mouse or pressing a key, and for which you can write code to respond. Events can occur as a result of a user action or program code, or they can be triggered by the system. You can also develop your own custom events to be raised by your objects and handled by other objects. For further information, see Events and Delegates.

See Also

Objects | Setting and Retrieving Properties | Performing Actions with Methods | Events and Delegates

Strings

The **String** data type represents a series of characters (each representing in turn an instance of the **Char** data type). An instance of a string can be assigned to a literal value that represents a series of characters. For example:

```
Dim MyString As String
MyString = "This is an example of the String data type"
```

A **String** variable can also accept any expression that evaluates to a string. Examples are shown below:

```
Dim OneString As String
Dim TwoString As String
OneString = "one, two, three, four, five"
TwoString = OneString.Substring(5,3)  ' Evaluates to "two".
OneString = "1"
TwoString = OneString & "1"  ' Evalates to "11".
```

Any literal that is assigned to a **String** variable must be enclosed by quotation marks (""). Naturally, this makes creating a literal that contains quotation marks somewhat problematic. For example, the following code returns a compiler error:

```
Dim myString As String
myString = "He said, "Look at this example!""  ' This causes an error.
```

This code returns a compiler error because the compiler terminates the string after the second quotation mark, leaving the rest of the string hanging. To have a quotation mark represented in a string literal, you must represent it as two quotation marks. The following example demonstrates the correct way to include a quotation mark in a string:

```
Dim myString As String
' The value of myString is: He said, "Look at this example!"
myString = "He said, ""Look at this example!"""
```

In the above example, the two quotation marks preceding the word 'Look' exist in the string as a single quotation mark. The three quotation marks at the end of the line represent a quotation mark in the string and the string termination character.

A string can be thought of as a series of **Char** instances, and the **String** type has built-in functions that allow you perform many manipulations on a string that resemble the manipulations allowed by arrays. You may refer to a specific character in a string through the **Chars** property, which provides a way to access a character by the position in which it appears in the string. For example:

```
Dim myString As String = "ABCDE"
Dim myChar As Char
myChar = myString.Chars(3)  ' The value of myChar is "C".
```

In the above example, the **Chars** property of the string returns the third character in the string, which is "C," and assigns it to `myChar`. You can also get the length of a particular string through the **Length** property. If greater array-type manipulation of the string is necessary, you can convert it to an array of **Char** instances using the **ToCharArray** function of the string. For example:

```
Dim myString As String = "abcdefghijklmnop"
Dim myArray As Char() = myString.ToCharArray
```

The variable `myArray` now contains an array of **Char** instances, each representing a character from `myString`.

The Immutability of Strings

A string is *immutable*, which means its value cannot be changed once it has been created. How, then, does the following example make any sense?

```
Dim myString As String = "This string is immutable"
myString = "Or is it?"
```

In the above example, it appears that a string is created, given a value, and then has that value changed. This appears to contradict the opening statement that strings are immutable. What is actually happening is that in the first line, an instance of **String** is created and given the value "This string is immutable". In the second line of the example, that *instance* is destroyed and a new instance is created and given the value "Or is it?". The only thing that doesn't change is the name of the variable.

Unlike other intrinsic data types, **String** is a reference type. When a variable of reference type is passed as an argument to a function or subroutine, a reference to the memory address where the data is stored is passed instead of the actual value of the string. So in the previous example, the name of the variable remains the same, but it points to a new and different instance of the **String** class, which holds the new value.

See Also

String Manipulation | String Class | Char Data Type

String Manipulation

The **String** class of the .NET framework provides many built-in methods to facilitate the comparison and manipulation of strings. It is now a trivial matter to get data about a string, or to create new strings by manipulating current strings. The Visual Basic .NET language also has inherent methods that duplicate many of these functionalities.

Types of String Manipulation Methods

In this section you will read about several different ways to analyze and manipulate your strings. Some of the methods are a part of the Visual Basic language, and others are inherent in the **String** class.

Visual Basic .NET methods are used as inherent functions of the language. They may be used without qualification in your code. The following example shows typical use of a Visual Basic .NET string-manipulation command:

```
Dim aString As String = "SomeString"
Dim bString As String
bString = Mid(aString, 3, 3)
```

In this example, the **Mid** function performs a direct operation on `aString` and assigns the value to `bString`.

You can also manipulate strings with the methods of the **String** class. There are two types of methods in **String**: *shared* methods and *instance* methods.

A shared method is a method that stems from the **String** class itself and does not require an instance of that class to work. These methods can be qualified with the name of the class (**String**) rather than with an instance of the **String** class. For example:

```
Dim aString As String
bString = String.Copy("A literal string")
```

In the preceding example, the **String.Copy** method is a static method, which acts upon an expression it is given and assigns the resulting value to `bString`.

Instance methods, by contrast, stem from a particular instance of **String** and must be qualified with the instance name. For example:

```
Dim aString As String = "A String"
Dim bString As String
bString = aString.SubString(2,6) ' bString = "String"
```

In this example, the **SubString** method is a method of the instance of **String** (that is, `aString`). It performs an operation on `aString` and assigns that value to `bString`.

Nothing and Strings

The Visual Basic runtime and the .NET Framework evaluate **Nothing** differently when it comes to strings. Consider the following example:

```
Dim MyString As String = "This is my string"
Dim stringLength As Integer
' Explicitly set the string to Nothing.
MyString = Nothing
' stringLength = 0
stringLength = Len(MyString)
' This line, however, causes an exception to be thrown.
stringLength = MyString.Length
```

The Visual Basic .NET runtime evaluates **Nothing** as an empty string; that is, "". The .NET Framework, however, does not, and will throw an exception whenever an attempt is made to perform a string operation on **Nothing**.

Comparing Strings

You can compare two strings by using the **String.Compare** method. This is a static, overloaded method of the base string class.

In its most common form, this method can be used to directly compare two strings based on their alphabetical sort order. This is similar to the Visual Basic StrComp Function function. The following example illustrates how this method is used:

```
Dim myString As String = "Alphabetical"
Dim secondString As String = "Order"
Dim result As Integer
result = String.Compare (myString, secondString)
```

This method returns an integer that indicates the relationship between the two compared strings based on the sorting order. A positive value for the result indicates that the first string is greater than the second string. A negative result indicates the first string is smaller, and zero indicates equality between the strings. Any string, including an empty string, evaluates to greater than a null reference.

Additional overloads of the **String.Compare** method allow you to indicate whether or not to take case or culture formatting into account, and to compare substrings within the supplied strings. For more information on how to compare strings, see String.Compare Method. Related methods include String.CompareOrdinal Method and String.CompareTo Method.

Searching for Strings Within Your Strings

There are times when it is useful to have data about the characters in your string and the positions of those characters within your string. A string can be thought of as an array of characters (**Char** instances); you can retrieve a particular character by referencing the index of that character through the **Chars** property. For example:

```
Dim myString As String = "ABCDE"
Dim myChar As Char
myChar = myString.Chars(3) ' myChar = "D"
```

You can use the **String.IndexOf** method to return the index where a particular character is encountered, as in the following example:

```
Dim myString As String = "ABCDE"
Dim myInteger As Integer
myInteger = myString.IndexOf("D")  ' myInteger = 3
```

In the previous example, the **IndexOf** method of `myString` was used to return the index corresponding to the first instance of the character "C" in the string. **IndexOf** is an overloaded method, and the other overloads provide methods to search for any of a set of characters, or to search for a string within your string, among others. The Visual Basic .NET command **InStr** also allows you to perform similar functions. For more information of these methods, see String.IndexOf Method and InStr Function. You can also use the String.LastIndexOf Method to search for the last occurrence of a character in your string.

Creating New Strings from Old

When using strings, you may want to modify your strings and create new ones. You may want to do something as simple as convert the entire string to uppercase, or trim off trailing spaces; or you may want to do something more complex, such as extracting a substring from your string. The **System.String** class provides a wide range of options for modifying, manipulating, and making new strings out of your old ones.

To combine multiple strings, you can use the concatenation operators (**&** or **+**). You can also use the String.Concat Method to concatenate a series of strings or strings contained in objects. An example of the **String.Concat** method follows:

```
Dim aString As String = "A"
Dim bString As String = "B"
Dim cString As String = "C"
Dim dString As String = "D"
Dim myString As String
' myString = "ABCD"
myString = String.Concat(aString, bString, cString, dString)
```

You can convert your strings to all uppercase or all lowercase strings using either the Visual Basic .NET functions UCase Function and LCase Function or the String.ToUpper Method and String.ToLower Method methods. An example is shown below:

```
Dim myString As String = "UpPeR oR LoWeR cAsE"
```

```
Dim newString As String
' newString = "UPPER OR LOWER CASE"
newString = UCase(myString)
' newString = "upper or lower case"
newString = LCase(myString)
' newString = "UPPER OR LOWER CASE"
newString = myString.ToUpper
' newString = "upper or lower case"
newString = myString.ToLower
```

The **String.Format** method and the Visual Basic .NET **Format** command can generate a new string by applying formatting to a given string. For information on these commands, see Format Function or String.Format Method.

You may at times need to remove trailing or leading spaces from your string. For instance, you might be parsing a string that had spaces inserted for the purposes of alignment. You can remove these spaces using the String.Trim Method function, or the Visual Basic .NET **Trim** function. An example is shown:

```
Dim spaceString As String = _
"        This string will have the spaces removed        "
Dim oneString As String
Dim twoString As String
' This removes all trailing and leading spaces.
oneString = spaceString.Trim
' This also removes all trailing and leading spaces.
twoString = Trim(spaceString)
```

If you only want to remove trailing spaces, you can use the String.TrimEnd Method or the **RTrim** function, and for leading spaces you can use the String.TrimStart Method or the **LTrim** function. For more details, see LTrim, RTrim, and Trim Functions functions.

The **String.Trim** functions and related functions also allow you to remove instances of a specific character from the ends of your string. The following example trims all leading and trailing instances of the "#" character:

```
Dim myString As String = "#####Remove those!######"
Dim oneString As String
OneString = myString.Trim("#")
```

You can also add leading or trailing characters by using the String.PadLeft Method or the String.PadRight Method.

If you have excess characters within the body of your string, you can excise them by using the String.Remove Method, or you can replace them with another character using the String.Replace Method. For example:

```
Dim aString As String = "This is My Str@o@o@ing"
Dim myString As String
Dim anotherString As String
' myString = "This is My String"
myString = aString.Remove(14, 5)
' anotherString = "This is Another String"
anotherString = myString.Replace("My", "Another")
```

You can use the **String.Replace** method to replace either individual characters or strings of characters. The Visual Basic .NET Mid Statement can also be used to replace an interior string with another string.

You can also use the String.Insert Method to insert a string within another string, as in the following example:

```
Dim aString As String = "This is My Stng"
Dim myString As String
' Results in a value of "This is My String".
myString = aString.Insert(13, "ri")
```

The first parameter that the **String.Insert** method takes is the index of the character the string is to be inserted after, and the second parameter is the string to be inserted.

You can concatenate an array of strings together with a separator string by using the String.Join Method. Here is an example:

```
Dim shoppingItem(2) As String
Dim shoppingList As String
shoppingItem(0) = "Milk"
shoppingItem(1) = "Eggs"
shoppingItem(2) = "Bread"
shoppingList = String.Join(",", shoppingItem)
```

The value of `shoppingList` after running this code is "Milk,Eggs,Bread". Note that if your array has empty members, the method still adds a separator string between all the empty instances in your array.

You can also create an array of strings from a single string by using the String.Split Method. The following example demonstrates the reverse of the previous example: it takes a shopping list and turns it into an array of shopping items. The separator in this case is an instance of the **Char** data type; thus it is appended with the literal type character **c**.

```
Dim shoppingList As String = "Milk,Eggs,Bread"
Dim shoppingItem(2) As String
shoppingItem = shoppingList.Split(","c)
```

The Visual Basic .NET Mid Function can be used to generate substrings of your string. The following example shows this functions in use:

```
Dim aString As String = "Left Center Right"
Dim rString, lString, mString As String
' rString = "Right"
rString = Mid(aString, 13)
' lString = "Left"
lString = Mid(aString, 1, 4)
' mString = "Center"
mString = Mid(aString, 6,6)
```

Substrings of your string can also be generated using the String.Substring Method. This method takes two arguments: the character index where the substring is to start, and the length of the substring. The **String.Substring** method operates much like the **Mid** function. An example is shown below:

```
Dim aString As String = "Left Center Right"
Dim subString As String
' subString = "Center"
subString = aString.SubString(5,6)
```

There is one very important difference between the **String.SubString** method and the **Mid** function. The **Mid** function takes an argument that indicates the character position for the substring to start, starting with position 1. The **String.SubString** method takes an index of the character in the string at which the substring is to start, starting with position 0. Thus, if you have a string "ABCDE", the individual characters are numbered 1,2,3,4,5 for use with the **Mid** function, but 0,1,2,3,4 for use with the **System.String** function.

Constants and Enumerations

Constants are a way to use meaningful names in place of a value that does not change. Constants store values that, as the name implies, remain constant throughout the execution of an application. Using constants allows you to provide meaningful names instead of numbers, making your code more readable.

Enumerations provide a convenient way to work with sets of related constants, and to associate constant values with names. For example, you can declare an enumeration for a set of integer constants associated with the days of the week, and then use the names of the days rather than their integer values in your code.

In This Section

Constants Overview
Describes constants and their uses.
Declaring Constants
Explains how to use the **Const** statement to declare a constant and set its value, thus assigning a meaningful name to the value.
User-Defined Constants
Describes how to create your own constants, including information on scoping and how to avoid circular references.
Constant and Literal Data Types

Enum Statement
Provides syntax and usage rules for the **Enum** statement, which is used to create enumerations.
Option Explicit Statement
Provides syntax and usage rules for the **Option Explicit** statement, which is used at module level to force explicit declaration of all variables in that module.
Option Strict Statement
Provides syntax and usage rules for the **Option Strict** statement, which restricts implicit data type conversions to widening conversions only.

Constants Overview

Code often contains constant values that reappear. It can also depend on certain numbers that are difficult to remember or have no obvious meaning.

In these cases, you can greatly improve the readability of your code and make it easier to maintain by using constants. A constant is a meaningful name that takes the place of a number or string that does not change. Constants store values that, as the name implies, remain constant throughout the execution of an application.

You declare a constant with the **Const** statement, using the same guidelines you would for creating a variable name. If **Option Strict** is **On**, you must explicitly declare the constant type.

A constant's scope is the same as that of a variable declared in the same location. To create a constant that exists within the scope of a particular procedure, declare it inside that procedure. To create a constant that is available throughout an application, declare it using the **Public** keyword in the declarations section of the class.

> **Note** Although constants somewhat resemble variables, you cannot modify them or assign new values to them as you can to variables.

The constants you use in your code can be intrinsic to the object model for controls or components you work with, or they can be user-defined (that is, those you create yourself).

Declaring Constants

You use the **Const** statement to declare a constant and set its value. By declaring a constant, you assign a meaningful name to a value. Once a constant is declared, it cannot be modified or assigned a new value.

You declare a constant within a procedure or in the declarations section of a module, class, or structure. Class or structure-level constants are **Private** by default, but may also be declared as **Public**, **Friend**, **Protected**, or **Protected Friend** for the appropriate level of code access.

The constant must have a valid symbolic name (the rules are the same as those for creating variable names) and an expression composed of numeric or string constants and operators (but no function calls).

To declare a constant

- Write a declaration that includes an access specifier, the **Const** keyword, and an expression, as in the following examples:

```
Public Const DaysInYear = 365
Private Const WorkDays = 250
```

When **Option Strict** is **On**, you must declare a constant explicitly by specifying a data type (**Boolean**, **Byte**, **Char**, **DateTime**, **Decimal**, **Double**, **Integer**, **Long**, **Short**, **Single**, or **String**). When **Option Strict** is **Off**, the constant is assigned a data type by the compiler. See Constant and Literal Data Types for more information.

To declare a constant with Option Strict On

- With **Option Strict On**, write a declaration that includes the **As** keyword and an explicit data type, as in the following examples:

```
Option Strict On
Public Const MyInteger As Integer = 42
Private Const DaysInWeek As Short = 7
Protected Friend Const Funday As String = "Sunday"
```

You can declare multiple constants on a single line, although your code is more readable if you declare only a single constant per line. If you declare multiple constants on a single line, they must all have the same access level (**Public**, **Private**, **Friend**, **Protected**, or **Protected Friend**).

To declare multiple constants on a single line

- Separate the declarations with a comma and a space, as in the following example:

```
Public Const Four As Integer = 4, Five As Integer = 5, Six As Integer = 44
```

Const Statement | Data Types | Constant and Literal Data Types | Constants and Enumerations | Enumerations Overview | Constants Overview | Declaring Enumerations | Enumerations and Name Qualification | Option Strict Statement | Intrinsic Constants and Enumerations | Choice of Variable Scope

User-Defined Constants

You can use constants that are intrinsic to the object model for controls or components you work with, or you can create your own. Constants you create yourself are described as being *user-defined*.

You declare a constant with the **Const** statement, using the same guidelines you would for creating a variable name. If **Option Strict** is **On**, you must explicitly declare the constant type.

Const Statement Usage

A **Const** statement can represent a mathematical or date/time quantity:

```
Const conPi = 3.14159265358979
Public Const conMaxPlanets As Integer = 9
Const conReleaseDate = #1/1/95#
```

It also can define **String** constants:

```
Public Const conVersion = "07.10.A"
Const conCodeName = "Enigma"
```

The expression on the right side of the equal sign (**=**) is often a number or literal string, but it also can be an expression that results in a number or string (although that expression cannot contain calls to functions). You can even define constants in terms of previously defined constants:

```
Const conPi2 = conPi * 2
```

Scope of User-Defined Constants

A **Const** statement's scope is the same as that of a variable declared in the same location. You can specify scope in any of the following ways:

- To create a constant that exists only within a procedure, declare it within that procedure.
- To create a constant available to all procedures within a class, but not to any code outside that module, declare it in the declarations section of the class.
- To create a constant that is available to all members of an assembly, but not to outside clients of the assembly, declare it using the **Friend** keyword in the declarations section of the class.
- To create a constant available throughout the application, declare it using the **Public** keyword in the declarations section the class.

For more information, see Declaring Constants and Choice of Variable Scope.

Avoiding Circular References

Because constants can be defined in terms of other constants, it is possible to inadvertently create a *cycle*, or circular reference, between two or more constants. A cycle occurs when you have two or more public constants, each of which is defined in terms of the other, as in the following example:

```
Public Const conA = conB * 2
Public Const conB = conA / 2
```

If a cycle occurs, Visual Basic generates a compiler error.

See Also

Const Statement | String Class | Constant and Literal Data Types | Declaring Constants | Option Strict Statement | Constants Overview | Enumerations Overview | Declaring Enumerations | Enumerations and Name Qualification | Intrinsic Constants and Enumerations | Choice of Variable Scope

Constant and Literal Data Types

When **Option Strict** is **On**, you must declare all constants explicitly with a data type. In the following example, the data type of `MyByte` is explicitly declared as data type **Byte**:

```
Option Strict On
Public Const MyByte As Byte = 2
```

Explicitly declaring data types is unambiguous, and typed code is easier to read and maintain than untyped code. When **Option Strict** is **Off**, however, the compiler uses the type of the expression used to initialize the constant. A numeric integer literal is cast by default to the **Integer** data type. The default data type for floating point numbers is **Double**, and the keywords **True** and **False** specify a **Boolean** constant.

Literals and Type Coercion

In some cases, you might want to force a literal to a particular data type; for example, when assigning a particularly large integral literal value to a variable of type **Decimal**. The following example produces an error:

```
Dim myDecimal as Decimal
myDecimal = 10000000000000000000   ' This causes a compiler error.
```

The error results from the representation of the literal. The **Decimal** data type can hold a value this large, but the literal is implicitly represented as a **Long**, which cannot.

You can coerce a literal to a particular data type in two ways: by appending a type character to it, or by placing it within enclosing characters. A type character or enclosing characters must immediately precede and/or follow the literal, with no intervening space or characters of any kind.

To make the previous example work, you can append the D type character to the literal, which causes it to be represented as a **Decimal**:

```
MyDecimal = 10000000000000000000D
```

The following example demonstrates correct usage of type characters and enclosing characters:

```
Option Strict Off
Public Const DefaultInteger = 100   ' Default is Integer.
Public Const DefaultDouble = 54.3345612   ' Default is Double.
Public Const MyCharacter = "a"C   ' Forces constant to be a Char type.
Public Const MyDate = #01/15/01#   ' Demonstrates DateTime constants.
Public Const MyTime = #1:15:59 AM#
Public Const MyLong = 45L   ' Forces data type to be a Long.
Public Const MySingle = 45.55!   ' Forces data type to be a Single.
```

The following table shows the enclosing characters and type characters available in Visual Basic.

Data type	Enclosing character	Appended type characte r
Boolean	(none)	(none)
Byte	(none)	(none)
Char	"	C
Date	#	(none)
Decimal	(none)	D or @
Double	(none)	R or #
Integer	(none)	I or %
Long	(none)	L or &
Short	(none)	S
Single	(none)	F or !
String	"	(none)

Enumerations Overview

Enumerations provide a convenient way to work with sets of related constants and to associate constant values with names. For example, you can declare an enumeration for a set of integer constants associated with the days of the week, and then use the names of the days rather than their integer values in your code.

You create an enumeration in the declarations section of a class or module, using the **Enum** statement.

An **Enum** type has a name, an underlying type, and a set of fields, each representing a constant. The name must be a valid Visual Basic .NET qualifier. The underlying type must be one of the integer types — **Byte**, **Short**, **Long** or **Integer**. **Integer** is the default. Enumerations are always strongly typed and are not interchangeable with integer number types.

You can assign the same value to multiple fields. When you do so, the compiler marks one of the **Enum** values as primary for purposes of string conversion and reflection. You can use an assignment statement to explicitly assign values to constants in an enumeration. All integer values, including negative numbers, are permissible.

For more information on using the **Enum** statement, see Declaring Enumerations.

See Also

Constants Overview | User-Defined Constants | Declaring Constants | Constant and Literal Data Types | Declaring Enumerations | Enumerations and Name Qualification | Intrinsic Constants and Enumerations

Declaring Enumerations

You create an enumeration with the **Enum** statement in the declarations section of a class or module. You cannot declare an enumeration within a method. To specify the appropriate level of code access, use **Private**, **Protected**, **Friend**, or **Public**.

To declare an enumeration

- Write a declaration that includes an access level, the **Enum** keyword, and a valid name, as in the following examples:

```
Private Enum MyEnum
Public Enum MyEnum
Protected Enum MyEnum
Friend Enum MyEnum
Protected Friend Enum MyEnum
```

By default, the first constant in an enumeration is initialized to 0, and subsequent constants are initialized to a value of one more than the previous constant. For example, the following enumeration, `Days`, contains a constant named `Sunday` with the value 0, a constant named `Monday` with the value 1, a constant named `Tuesday` with the value of 2, and so on:

```
Public Enum Days
   Sunday
   Monday
   Tuesday
   Wednesday
   Thursday
   Friday
   Saturday
End Enum
```

You can explicitly assign values to constants in an enumeration by using an assignment statement. You can assign any integer value, including negative numbers. For example, you may want constants with values less than zero to represent error conditions.

In the following enumeration, the constant `Invalid` is explicitly assigned the value –1, and the constant `Sunday` is assigned the value 0. Because it is the first constant in the enumeration, `Saturday` is also initialized to the value 0. The value of `Monday` is 1 (one more than the value of `Sunday`); the value of `Tuesday` is 2, and so on:

```
Public Enum WorkDays
   Saturday
   Sunday = 0
   Monday
   Tuesday
   Wednesday
   Thursday
   Friday
   Invalid = -1
End Enum
```

By default, enumerations are of the **Integer** type. You can explicitly declare them as **Integer**, **Short**, **Long**, or **Byte**.

To declare an enumeration explicitly

- Write a declaration using the following syntax:

```
Public Enum MyEnum As Byte
   Zero
   One
   Two
End Enum
```

Enumerations cannot have floating-point values. If an enumeration is assigned a floating-point value with **Option Strict On**, a compiler error results. If **Option Strict** is **Off**, the value is automatically converted to the **Enum** type.

For information on names, and how to use the **Imports** statement to make name qualification unnecessary, see Enumerations and Name Qualification.

Enumerations Overview | Enumerations and Name Qualification | Intrinsic Constants and Enumerations | Constants Overview | User-Defined Constants | Declaring Constants | Constant and Literal Data Types

Enumerations and Name Qualification

Normally, when referring to a member of your enumeration, you must qualify the member name with the enumeration name. For example, to refer to the `Sunday` member of your `Days` enumeration, you would use the following syntax:

```
X = Days.Sunday
```

You can avoid using fully qualified names by adding an **Imports** statement to the namespace declarations section of your code, as in the following example:

```
Imports WindowsApplication1.Form1.Days
```

An **Imports** statement imports namespace names from referenced projects and assemblies, and from within the same project as the module in which the statement appears. Once this statement is added, you can refer to your enumeration members without qualification, as in the following example:

```
X = Sunday
```

By organizing sets of related constants in enumerations, you can use the same constant names in different contexts. For example, you can use the same names for the weekday constants in the `Days` and `WorkDays` enumerations. If you use the **Imports** statement with your enumerations, you must be careful to avoid ambiguous references. Consider the following example:

```
Imports WindowsApplication1.Form1.Days
Imports WindowsApplication1.Form1.WorkDays
Public Sub New()
   ' Insert code to implement constructor.
   ' Ambiguous reference. Does it refer to Days.Monday or WorkDays.Monday?
X = Monday
End Sub
```

Assuming that `Monday` is a member of both the `Days` enumeration and the `Workdays` enumeration, this code generates a compiler error. To avoid ambiguous references when referring to an individual constant, qualify the constant name with its enumeration. The following code refers to the `Saturday` constants in the `Days` and `WorkDays` enumerations.

```
X = Days.Saturday
Y = WorkDays.Saturday
```

Intrinsic Constants and Enumerations

Visual Basic .NET provides a number of intrinsic constants and enumerations to facilitate your programming.

Constants store values that remain constant throughout the execution of an application. They are meaningful names that take the place of a number or string and make code more readable. Enumerations offer an easy way to work with sets of related constants. An enumeration, or Enum, is a symbolic name for a set of values.

In the following enumeration, `SchoolDays`, the constant `NotValid` is assigned the value of -1, and the constant `Sunday` is assigned the value of 0. Because it is the first constant, `Saturday` is also initialized to a value of 0. The value of `Monday` is 1 (one more than the value of `Sunday`, the immediately preceding value); the value of `Tuesday` is 2 (one more than `Monday`, the immediately preceding value).

```
Public Enum SchoolDays
   Saturday
   Sunday = 0
   Monday
   Tuesday
   Wednesday
   Thursday
   Friday
   NotValid = -1
End Enum
```

You can create your own constants and enumerations, as discussed in User-Defined Constants, or you can use the intrinsic constants and enumerations Visual Basic .NET provides, which are listed in the Object Browser. The following table lists the intrinsic enumerations available in Visual Basic .NET.

Enumeration	**Used with**
AppWinStyle	Shell commands
CallType	**CallByName** function
CompareMethod	Comparison functions
DateFormat	DateValue function
FileAttribute	**Dir**, **GetAttr** and **SetAttr** functions
FirstDayOfWeek	Date related functions
FirstWeekOfYear	Date related functions
MsgBoxResult	**MsgBox** function
MsgBoxStyle	**MsgBox** function
Tristate	Number-formatting functions
VbStrConv	**StrConv** function

Operators

An operator is a code unit that performs an operation on one or more value-returning code elements. Such an operation can be an arithmetic operation such as addition or multiplication; a concatenation operation that combines two strings into a new string; a comparison operation that determines which of two values is greater; a logical operation evaluating whether two expressions are both true. Operators combined with value-returning code elements such as literals or variables form expressions, or in the case of the assignment operator, statements.

The following is an example of a statement that uses the simple assignment operator (**=**):

```
x = 45
```

In the preceding example, the assignment operator performs the assignment operation: it takes the value on the right side of the operator and assigns it to the variable on the left. Several operators can perform actions in a single expression or statement, as demonstrated below:

```
x = 45 + y * z ^ 2
```

In this example, the operations in the expression on the right side of the assignment operator are performed, and the resulting value is assigned to the variable `x`, on the left. There is no limit to the number of operators that can be combined into an expression, but an understanding of Operator Precedence in Visual Basic is necessary to ensure that you get the results you expect. For more information, see Efficient Combination of Operators.

Arithmetic Operators

Arithmetic operators are used to perform many of the familiar arithmetic operations that involve the calculation of numeric values represented by literals, variables, other expressions, function and property calls, and constants.

Arithmetic Operations

You can add two values in an expression together with the **+** operator, or subtract one from another with the **-** operator, as shown in the following examples:

```
Dim x As Integer
x = 67 + 34
x = 32 - 12
```

Negation also uses the **-** operator, but with somewhat different syntax, as shown below:

```
Dim x As Integer = 65
Dim y As Integer
y = -x
```

Multiplication and division use the ***** and **/** operators, respectively, as in these examples:

```
Dim y As Double
y = 45 * 55.23
y = 32 / 23
```

Exponentiation uses the **^** operator, as shown below:

```
Dim z As Double
z = 23 ^ 3    ' z equals the cube of 23.
```

Integer division is carried out using the **** operator. Integer division returns the number of times one integer can evenly divide into another. Only integral types (**Byte**, **Short**, **Integer**, and **Long**) can be used with this operator. All other types must be converted to an integral type first. The following is an example of integer division:

```
Dim k As Integer
k = 23 \ 5      ' k = 4
```

Modulus arithmetic is performed using the **Mod** operator. This operator returns the remainder after the divisor is divided into the dividend an integral number of times. If both divisor and dividend are integral types, the returned value is integral. If divisor and dividend are floating-point types, the returned value is a floating point variable. Two examples illustrate this behavior:

```
Dim x As integer = 100
Dim y As Integer = 6
Dim z As Integer
z = x Mod y   ' z equals 4.
Dim a As Double = 100.3
Dim b As Double = 4.13
Dim c As Double
c = a Mod b   ' c equals 1.18.
```

Division by Zero

Division by zero has different results depending on the data types involved. In integral divisions (**Short**, **Integer**, **Long**), a **System.DivideByZeroException** is thrown. In division operations on the **Decimal** or **Single** data type, Visual Basic also throws a **System.DivideByZeroException** exception. In floating-point divisions with the **Double** variable type, however, the result is the class member representing **NaN**, **PositiveInfinity**, or **NegativeInfinity**, depending on the dividend. The following table summarizes the various results of attempting to divide by zero.

Dividend data type	Divisor data type	Dividend value	Result
Double	**Double**	0	**System.Double.NaN** (not a number)
Double	**Double**	> 0	**System.Double.PositiveInfinity**
Double	**Double**	< 0	**System.Double.NegativeInfinity**

When you catch a **System.DivideByZeroException** exception, you can use its members to help you handle it. The **HelpLink** property has a link to the appropriate help file, the **Message** property holds the message text for the exception, and the **StackTrace** property contains the trace, which should indicate where the error occurred. The **GetBaseException** method returns the original exception that caused this **DivideByZeroException**, as well as any other exceptions linked to it.

Bitwise Operations

Bitwise operations evaluating two values in binary (base 2) form, compare the bits at corresponding positions, and then assign values based on the comparison, as in the demonstration below of bitwise **And**:

```
Dim x As Integer
x = 3 And 5   ' x = 1
```

In this example, the value of `x` is `1`. Here's why:

- First, the values are converted to binary form, as shown below:

  3 in binary form = 011

  5 in binary form = 101

- Next, the binary representations are compared, one binary position at a time. If both bits at a given position are 1, then a 1 is placed in that position in the result. If either bit is 0, then a 0 is placed in that position in the result. In our example this works out as follows:

  011 3 in binary form

  101 5 in binary form

  001 The result, in binary form

  Converting back to decimal, 001 is the binary representation of 1, so x = 1.

The bitwise **Or** operation is similar, except that a 1 is assigned to the result bit if either of the compared bits is 1. **Xor** assigns a 1 to the result bit if only one of, but not both of, the compared bits is 1. **Not** takes a single operand and inverts all the bits, including the sign bit, and assigns that value to the result. This means that for positive numbers, **Not** always returns a negative. Likewise, for negative numbers, **Not** always returns a positive or zero.

> **Note** Bitwise operations can be performed on integral types only. Floating point values must be converted to integral types before bitwise operation can proceed.

Bit Shift Operations

A bit shift operation performs an arithmetic shift on a bit pattern. The pattern is contained in the operand on the left, while the operand on the right specifies the number of positions to shift the pattern. The data type of the pattern operand must be **Byte**, **Short**, **Integer**, or **Long**. The data type of the shift amount operand must be **Integer** or must widen to **Integer**.

Arithmetic shifts are not circular, which means the bits shifted off one end of the result are not reintroduced at the other end. The bit positions vacated by a shift are set as follows:

- Zero for an arithmetic left shift
- Zero for an arithmetic right shift of a positive number
- Zero for an arithmetic right shift of any pattern with data type **Byte**
- One for an arithmetic right shift of a negative number (**Short**, **Integer**, or **Long**)

In the following example, an **Integer** value is shifted both left and right:

```
Dim Pattern As Integer = 12   ' Low-order bits are 0000 1100
Dim LResult, RResult As Integer
LResult = Pattern << 3   ' Left shift of 3 bits produces value of 96
RResult = Pattern >> 2   ' Right shift of 2 bits produces value of 3
```

Arithmetic shifts never generate overflow exceptions.

Type Safety

Operands should normally be of the same type. For example, if you are adding an **Integer** variable, you should add it to another **Integer** variable, and the variable that the value is assigned to should be of type **Integer** as well.

One way to ensure good type-safe coding practice is to use **Option Strict**. If **Option Strict** is **On,** Visual Basic .NET automatically performs type-safe conversions. Thus, if you try to add an **Integer** variable to a **Double** variable and assign the value to a **Double** variable, the operation proceeds normally. Unsafe, or narrowing conversions, on the other hand, cause a compiler error. Thus if you try to add an **Integer** variable to a **Double** variable and assign the value to an **Integer** variable, a compiler error results, because a **Double** variable cannot be implicitly converted to type **Integer**.

If **Option Strict** is **Off**, however, these implicit narrowing conversions are allowed to take place, but can result in the unexpected loss of data or precision. For this reason, it is recommended that you use **Option Strict On** when writing production code. For additional information about conversions, see Widening and Narrowing Conversions, and for information about **Option Strict**, see Option Strict Statement.

DivideByZeroException Class | Widening and Narrowing Conversions | Option Strict Statement | Arithmetic Operators | Bit Shift Operators

Comparison Operators

Comparison operators compare two expressions and return a **Boolean** value that represents the result of the comparison. There are operators for comparing numeric values, operators for comparing strings, and operators for comparing objects. All three types of operators are discussed below.

Comparing Numeric Values

Numeric values are compared using six numeric comparison operators. The following table lists the operators and gives an example of the condition tested by the operator.

Operator	Condition tested	Examples

= (Equality)	Is the value represented by the first expression equal to the value represented by the second?	`23 = 33  ' False`
		`23 = 23  ' True`
		`23 = 12 ' False`

<> (Inequality)	Is the value represented by the first expression not equal to the value represented by the second?	`23 <> 33  ' True`
		`23 <> 23  ' False`
		`23 <> 12 ' True`

< (Less than)	Is the value represented by the first expression less than the value represented by the second?	`23 < 33  ' True`
		`23 < 23  ' False`
		`23 < 12 ' False`

> (Greater than)	Is the value represented by the first expression greater than the value represented by the second?	`23 > 33  ' False`
		`23 > 23  ' False`
		`23 > 12 ' True`

<= (Less than or equal to)	Is the value represented by the first expression less than or equal to the value represented by the second?	`23 <= 33  ' True`
		`23 <= 23  ' True`
		`23 <= 12 ' False`

>= (Greater than or equal to)	Is the value represented by the first expression greater than or equal to the value represented by the second?	`23 >= 33  ' False`
		`23 >= 23  ' True`
		`23 >= 12 ' True`

Comparing Strings

Strings can be compared using the **Like** operator as well as using the numeric comparison operators. The **Like** operator allows you to specify a pattern; the string is then compared against the pattern, and if it matches, the result is **True**. Otherwise, the result is **False**. The numeric operators allow you to compare **String** values based on their sort order, as in this example:

```
"73" < "9"    ' This result is True.
```

The result is **True** because the first character in the first string sorts before the first character in the second string. If the first characters were equal, the comparison would continue to the next character in both strings, and so on. Equality of strings can also be tested using the equality operator, as in this example:

```
"734" = "734"      ' The result is True.
```

In this example, the two strings are directly compared, and, because they are equal, **True** is returned.

If one string is a prefix of another, such as "aa" and "aaa", the longer string sorts after the shorter. Thus the following expression is true:

```
"aaa" > "aa"
```

The sort order will be based on either a binary comparison or a textual comparison depending on the Option Compare setting. For more information see Option Compare Statement.

Comparing Objects

You can use the **Is** operator to determine if two object variables refer to the same instance of an object. For example:

```
Dim x As MyClass
Dim y As New MyClass()
x = y
If x Is y Then
   ' Insert code to continue program execution.
```

In this example, `x Is y` evaluates to **True**, because both variables refer to the same instance. Contrast this result with the following example:

```
Dim x As New MyClass()
Dim y As New MyClass()
If x Is y then
   ' Insert code to continue program execution.
```

In this example, `x Is y` evaluates to **False**, because although the variables are of the same type, they refer to different instances of that type.

You can test whether an object is of a particular type with the **TypeOf...Is** operator. . The syntax is

```
    TypeOf <object expression> Is <TypeName>
```

When TypeName specifies an interface type then the TypeOf ... Is operator returns true if the object implements the interface type. When the TypeName is a class type then the operator returns true if the object is an instance of the specified class or is an instance of a class that derives from the specified class. For example:

```
Dim x As Button
x = New Button()
If TypeOf x Is Control Then
   ' Insert code to continue program execution.
```

Since the type of `x` is `Button`, and `Button` inherits from `Control`, the `TypeOf x Is Control` expression evaluates to **True**.

Value Comparisons | Comparison Operators | Operators

Concatenation Operators

Concatenation operators join multiple strings into a single string. There are two concatenation operators, **+** and **&**; both carry out the basic concatenation operation, as shown below:

```
Dim x As String
x = "Con" & "caten" & "ation"   ' x equals "Concatenation".
x = "Con" + "caten" + "ation"   ' x equals "Concatenation".
```

These operators can also concatenate **String** variables, as in the following example:

```
Dim x As String = "abc"
Dim y As String = "def"
Dim z As String
z = x & y   ' z equals "abcdef".
z = x + y   ' z equals "abcdef".
```

If **Option Strict** is **On**, the **+** operator explicitly requires strings for concatenation operations. It also carries out arithmetic operations with numeric operands when **Option Strict** is **On**. If **Option Strict** is **Off**, however, the **+** operator supports a wide variety of implicit conversions for concatenation operations. For further information on these conversions, see + Operator.

The **&** operator is defined only for **String** operands, and it always widens its operands to **String**, regardless of the setting of **Option Strict**. The **&** operator is recommended for string concatenation because it is defined exclusively for strings and reduces your chances of generating an unintended conversion.

See Also

& Operator | + Operator | Option Strict Statement | String Manipulation

Logical Operators

The logical operators compare **Boolean** expressions and return a **Boolean** result. The **And**, **Or**, **AndAlso**, **OrElse**, and **Xor** operators take two operands, and the **Not** operator takes a single operand.

The **Not** operator performs logical negation on a **Boolean** expression. Put simply, it yields the opposite of the expression it evaluates. If the expression evaluates to **True**, **Not** yields **False**; if the expression evaluates to **False**, **Not** yields **True**. An example is shown below:

```
Dim x As Boolean
x = Not 23 > 12   ' x equals False.
x = Not 23 > 67   ' x equals True.
```

The **And** operator performs logical conjunction on two **Boolean** expressions. That is, if both expressions evaluate to **True**, then the **And** operator returns **True**. If either or both expressions evaluate to **False**, then **And** returns **False**.

The **Or** operator performs logical disjunction on two **Boolean** expressions. If either expression evaluates to **True**, **Or** returns **True**. If neither expression evaluates to **True**, **Or** returns **False**.

Xor performs logical exclusion on two expressions. If either expression evaluates to **True**, but not both, **Xor** returns **True**. If both expressions evaluate to **True** or both expressions evaluate to **False**, **Xor** returns **False**.

Examples of the **And**, **Or**, and **Xor** operators are shown below:

```
Dim x As Boolean
x = 23 > 12 And 12 >4   ' x = True
x = 12 > 23 And 12 > 4   ' x = False
x = 23 > 12 Or 4 > 12`   ' x = True
x = 23 > 45 Or 4 > 12   ' x = False
x = 23 > 45 Xor 12 > 4   ' x = True
x = 23 > 12 Xor 12 > 4   ' x = False
x = 12 > 23 Xor 4 > 12   ' x = False
```

> **Note** In addition to being logical operators, **Not**, **Or**, **And**, and **Xor** also perform bitwise arithmetic when used on numeric values. Information on this functionality can be found at Arithmetic Operators.

The **AndAlso** operator is very similar to the **And** operator, in that it also performs logical conjunction on two **Boolean** expressions. The key difference between **AndAlso** and **And** is that **AndAlso** exhibits short-circuiting behavior. If the first expression in an **AndAlso** expression evaluates to **False**, then the second expression is not evaluated and **False** is returned for the **AndAlso** expression.

Similarly, the **OrElse** operator performs short-circuiting logical disjunction on two **Boolean** expressions. If the first expression in an **OrElse** expression evaluates to **True**, then the second expression is not evaluated and **True** is returned for the **OrElse** expression. Below are some examples that illustrate the difference between **And**, **Or**, and their counterparts:

```
12 > 45 And MyFunction(4) ' MyFunction() is called.
12 > 45 AndAlso MyFunction(4)   ' MyFunction() is not called.
45 > 12 Or MyFunction(4)   ' MyFunction is called.
45 > 12 OrElse MyFunction(4)   ' MyFunction is not called
```

In the first example, `MyFunction()` is called, even though `12 > 45` returns **False**, because **And** does not short circuit. In the second example, `MyFunction` is not called, because `12 > 45` returns **False**, so **AndAlso** short circuits the second expression. In the third example, `MyFunction` is called, even though `45 > 12` returns **True**, because **Or** does not short circuit. In the fourth example, `MyFunction` is not called because `45 > 12` returns **True**, so **OrElse** short circuits the second expression.

> **Note** Although **And** and **Or** support bitwise operations with numeric values, **AndAlso** and **OrElse** do not.

Logical/Bitwise Operators | Arithmetic Operators | Boolean Expressions | Efficient Combination of Operators

Efficient Combination of Operators

Complex expressions can contain many different operators. Consider the following statement:

```
x = (45 * (y + z)) ^ (2 / 85) * 5 + z
```

Creating complex expressions such as these requires a thorough understanding of the rules of operator precedence. This topic, which will help you construct efficient expressions, assumes that you are familiar with the rules of operator precedence. For more information, see Operator Precedence in Visual Basic.

Numeric Expressions

In numeric expressions such as the one in the above example, operators follow a strict precedence pattern. First, any variables or properties are read, and any value-returning function calls are executed.

Once these values are retrieved, the expression is evaluated in accordance with the rules of operator precedence. Exponentiation (**^**) occurs first, then negation (**-**). These are followed by multiplication (*****) and division (**/**), which have equal operator precedence and therefore occur in textual order from left to right. Integer division (****) occurs next, followed by modulus arithmetic (**Mod**). Addition (**+**) and subtraction (**-**) take place next; Logical/Bitwise Operators evaluate last. When operators of equal precedence occur in an expression, evaluation is in the order of operator occurrence, from left to right.

Boolean Expressions

Boolean expressions can be even more complex than numeric expressions, since they can combine arithmetic operators, comparison operators, and logical operators. The following is an example of an expression that contains all three kinds:

```
x + y > z And z + y < w
```

In this example, arithmetic operations are performed by the `+` operator, comparison operations are performed by the `>` and `<` operators, and a logical operation is performed by the `And` operator. When evaluating an expression with different kinds of operators, standard operator precedence usually determines the order of operation. For details, see Operator Precedence in Visual Basic.

Parenthetical Expressions

Often you want the execution of operations to proceed in a different order from that determined by operator precedence. Consider this example:

```
x = z * y + 4
```

In this example, `z` is multiplied by `y`, and then the result is added to `4`. But what if you want to add `y` and `4` before multiplying by `z`? In such a case you can override normal operator precedence by using parentheses. By enclosing an expression in parentheses, you force that expression to evaluate first, regardless of operator precedence.

So, to force the above expression to evaluate addition first, you would rewrite the example as follows:

```
x = z * (y + 4)
```

The value of `y` is now added to `4`, and that sum is multiplied by `z`.

You can nest expressions in multiple levels of parentheses to enforce precedence further. The expressions most deeply nested in parentheses are granted primary precedence, followed by less deeply nested expressions, and so on. Consider the following example:

```
x = (z * 4) ^ (y * (z + 2))
```

Here, `z + 2` has primary precedence, then the other parenthetical expressions. Exponentiation, which normally has higher precedence than addition or multiplication, evaluates last in this example because the other expressions are enclosed in parentheses.

Expressions

An expression can be thought of as a series of value-representing elements, separated by operators, that yields a new value. Examples of such value-representing elements are literals, variables, other expressions, and function calls. The operators act upon the value-representing elements by performing calculations, comparisons, or other operations. The end result of the expression represents a value, which can be either numeric, **Boolean**, or **String**.

The following are examples of expressions:

```
5 + 4   ' Evaluates to 9.
15 * System.Math.Sqrt(9) + x    ' Evaluates to 45 plus the value of x.
"Concat" & "ena" + "tion"   ' Evaluates to "Concatenation".
763 < 23   ' Evaluates to False.
x Is y   ' Value depends on the objects represented by x and y.
```

Calculating Numeric Values

Numeric values can be calculated through the use of numeric expressions. A numeric expression is an expression that contains literals and variables representing numeric values, and operators that act upon those values. The following is an example of a numeric expression:

```
4 * (67 + x) ' For the purposes of this example, x = 2.
```

This expression evaluates to 276, which is the value of 67 plus 2, multiplied by 4.

If the numeric expression contains more than one operator, the order in which they are evaluated is determined by the rules of operator precedence. To override the rules of operator precedence, you enclose expressions in parentheses, as in the above example; such expressions are evaluated first. For more information, see Operator Precedence in Visual Basic, and Efficient Combination of Operators

You can use an assignment statement to assign the value represented by this expression to another variable, as in this example:

```
Dim x As Integer = 2
Dim y As Integer
y = 4 * (67 + x)
```

Here, the value of the expression on the right side of the operator is assigned to the variable `y` on the left side of the operator, so `y` evaluates to 276. For more information on assignment, see Assignment Statements.

Expressions | Value Comparisons | Assignment Statements | Operator Precedence in Visual Basic | Arithmetic Operators | Efficient Combination of Operators

Value Comparisons

Comparison operators can be used to construct expressions that compare the values of numeric variables. These expressions return a **Boolean** value based on whether the comparison is true or false. Examples of such an expression would be:

```
45 > 26
26 > 45
```

The first expression evaluates to **True**, because 45 is greater than 26. The second example evaluates to **False**, because 26 is not greater than 45.

You can compare any two numeric expressions in this fashion. The expressions you compare can themselves be complex expressions, as in this example:

```
x / 45 * (y +17) >= System.Math.Sqrt(z) / (p - (x * 16))
```

This complex expression includes literals, variables, and function calls. The expressions on both sides of the comparison operator are evaluated, and the resulting values are then compared using the **>=** comparison operator. If the value of the expression on the left side is greater than or equal to the value of the expression on the right, the entire expression evaluates to **True**; otherwise, it evaluates to **False**.

Expressions that compare values are most commonly used in **If...Then** statements, as in the following example:

```
If x > 50 Then
   ' Insert code to be executed if x is greater than 50.
Else
   ' Insert code to be executed if x is less than or equal to 50.
End If
```

The **=** sign is a comparison operator as well as an assignment operator. When used as a comparison operator, it evaluates whether the value on the left is equal to the value on the right, as shown in the following example:

```
If x = 50 Then
   ' Insert code to continue program.
End If
```

You can also use a comparison expression anywhere that a **Boolean** value is needed such as in an **If**, **While**, **Loop**, **ElseIf** statement or when assigning to or passing a value to a Boolean variable. In the following example, the value returned by the comparison expression is assigned to a **Boolean** variable:

```
Dim x As Boolean
x = 50 < 30   ' x is assigned False.
```

Boolean Expressions | Operators | Comparison Operators | Expressions | Calculating Numeric Values | Operator Precedence in Visual Basic

Boolean Expressions

A **Boolean** expression is an expression that evaluates to a **Boolean** value. **Boolean** expressions can take several forms. The simplest is the direct comparison of the value of a **Boolean** variable to a **Boolean** literal, as shown in this example:

```
If x = True Then   ' Compares x to the Boolean value True.
   ' Insert code to execute if x = True.
Else
   ' Insert code to execute if x = False.
End If
```

Note that the assignment statement `x = True` looks the same as the expression in the example, but it performs a different function and is used differently. In the above example, the expression `x = True` represents a value, and thus the = sign is interpreted as a comparison operator. In a stand-alone statement, it would be interpreted as an assignment operator and assign the value on the right to the variable on the left. The following example illustrates this:

```
If x = True then   ' Compare the value of x to Boolean value True.
   y = False      ' Assign the Boolean value True to variable y.
End If
```

For further information, see Value Comparisons and Assignment Statements.

Comparison operators, such as =, **<**, **>**, **<>**, **<=**, and **>=**, produce **Boolean** expressions by comparing the expression on the left side of the operator to the expression on the right side of the operator and evaluating the result as true or false. For instance:

```
42 < 81   ' Evaluates to True.
```

For more information on this kind of expression, see Value Comparisons.

Comparison expressions can be combined using logical operators to produce more complex **Boolean** expressions. The following example demonstrates the use of comparison operators in conjunction with a logical operator:

```
x > y And x < 1000
```

In the example, the value of the overall expression depends on the values of the expressions on each side of the **And** operator. If both expressions are true, then the overall expression evaluates as **True**. If either expression is false, then the entire expression evaluates to **False**.

Short-Circuiting Operators

The logical operators **AndAlso** and **OrElse** exhibit behavior known as *short-circuiting*. A short-circuiting operator evaluates the left expression first. If the left expression falsifies (in the case of **AndAlso**) or validates (in the case of **OrElse**) the entire expression, then program execution proceeds without evaluating the right expression. Take the following example:

```
If 45 < 12 AndAlso MyFunction(3) = 81 Then
   ' Add code to continue execution.
```

In this example, the operator evaluates the left expression, `45 < 12`. Since this expression evaluates to **False**, the entire logical expression evaluates to **False**. Program execution thus begins execution of the code within the If block without evaluating the right expression, `MyFunction(3)`. In this example, `MyFunction()` is never called because the left expression falsifies the entire expression.

Similarly, if the left expression in a logical expression using **OrElse** evaluates to **True**, execution proceeds to the next line of code without evaluating the second expression because the first expression has already enabled the entire expression.

By contrast, both sides of the logical operator are evaluated when the logical operators **And** and **Or** are used. Consider the following expression for example:

```
If 45 < 12 And MyFunction(3) = 81 Then
   ' Add code to continue execution.
```

In this example, a call is made to `MyFunction()`, even though the first expression evaluates to **False**.

Parenthetical Expressions

You can use parentheses to control the evaluation of **Boolean** expressions. Expressions enclosed by parentheses evaluate first. For multiple levels of nesting, precedence is granted to the most deeply-nested expressions. Within parentheses, evaluation proceeds according to the rules of operator precedence. For more information, see Operator Precedence in Visual Basic and Efficient Combination of Operators.

Statements

A *statement* in Visual Basic is a complete instruction that can contain keywords, operators, variables, constants, and expressions. All statements fall into one of two categories: *declaration statements*, which name a variable, constant, or procedure and can also specify a data type; or *executable statements*, which initiate actions.

In This Section

Statements Overview
: Provides a high-level look at statements, including how to have multiple statements on one line, continue a statement over multiple lines, add comments, and check compilation errors.

Assignment Statements
: Describes statements that carry out assignment operations, which assign the value on the right side of the operator to the variable on the left side.

Declaration Statements
: Describes statements that name and define procedures, variables, arrays, and constants.

Executable Statements
: Describes statements that initiate action by executing a method. Executable statements can loop or branch through blocks of code, and often contain mathematical or conditional operators.

Related Sections

Expressions
: Shows how to combine elements with operators to yield new values.

Operators
: Describes the code units that manipulate value-returning elements, and how to use them efficiently.

Statements Overview

A statement in Visual Basic is a complete instruction. It can contain keywords, operators, variables, constants, and expressions. Each statement belongs to one of the following two categories:

- Declaration statements, which name a variable, constant, or procedure and can also specify a data type. For more information, see Declaration Statements.
- Executable statements, which initiate actions. These statements can execute a method or function, and they can loop or branch through blocks of code. Executable statements include assignment statements, which assign a value or expression to a variable or constant. For more information, see Executable Statements and Assignment Statements.
- Declaration statements, which name a variable, constant, or procedure and can also specify a data type. For more information, see Declaration Statements.
- Executable statements, which initiate actions. These statements can execute a method or function, and they can loop or branch through blocks of code. Executable statements include assignment statements, which assign a value or expression to a variable or constant. For more information, see Executable Statements and Assignment Statements

Having Multiple Statements on One Line

You can have multiple statements on a single line separated by the colon (:) character. For example:

```
Dim MyString As String = "Hello World" : MsgBox(MyString)
```

Though occasionally convenient, this form of syntax makes your code hard to read and maintain. Thus, it is recommended that you keep one statement to a line.

Continuing a Statement over Multiple Lines

A statement usually fits on one line, but when it doesn't, you can continue a long statement onto the next line using a line-continuation character, which consists of an underscore character (_) followed by a carriage return. In the following example, the **MsgBox** executable statement is continued over two lines:

```
Public Sub DemoBox()   'This procedure displays a message.
   Dim myVar As String
   myVar = "John"
   MsgBox("Hello " & myVar & _
      ". How are you?")
End Sub
```

Adding Comments

Source code is not always self-explanatory, even to the programmer who wrote it. To help document their code, therefore, most programmers make liberal use of embedded comments. Comments in code can explain a procedure or a particular instruction to anyone reading or working with it later. Visual Basic ignores comments, however, when it runs your procedures.

Comment lines begin with an apostrophe (') or **REM** followed by a space, and can be added anywhere in code. To append a comment to a statement, insert an apostrophe or **REM** after the statement, followed by the comment. Such a comment appears in the preceding example. Comments can also go on their own separate line.

Checking Compilation Errors

If, after you type a line of code, the line is displayed with a wavy blue underline (an error message may display as well), there is a syntax error in the statement. You must find out what's wrong with your statement (by looking in the task list, or hovering over the error and reading the help text, for example) and correct it. Until you have fixed all syntax errors in your code, your program will fail to compile correctly.

See Also

Assignment Statements | Declaration Statements | Executable Statements | Labeling Statements

Assignment Statements

Assignment statements carry out assignment operations. Simple assignment operations consist of taking the value on the right side of the operator and assigning it to the variable on the left, as in this example:

```
x = 42
```

Here, the variable `x` is assigned the literal value 42.

The value on the right side of the operator can be any literal, variable, expression, or function call that returns a value, as in this example:

```
x = y + z + MyFunction(3)
```

Here, the value represented by `y` is added to the value represented by `z`, which is added to the value returned by the call to `MyFunction(3)`. The total value of this expression is then assigned to the variable `x`.

The assignment operator can also assign values to **String** variables and **String** expressions, as in this example:

```
Dim x As String
x = "String variable assignment"
x = "Con" & "cat" & "enation" ' x equals "Concatenation".
```

The values of **Boolean** variables can be assigned as well, using either a **Boolean** literal or a **Boolean** expression as the right argument:

```
Dim x As Boolean
x = True
x = 45 > 1003 ' x equals False.
x = 45 > 1003 Or 45 > 17 ' x equals True.
```

The argument on the left side of the operator can be any valid variable or property. The following example demonstrates setting the value of the text property of a text box:

```
MyTextBox.Text = "This " & "is a " & "String"
   ' MyTextBox.Text = "This is a String".
```

Other assignment statements first perform an operation on an argument before assigning it to another argument. The following example illustrates one of these operators, **+=**, which increments the value of the variable on the left side of the operator by the value of the expression on the right:

```
x += 1
```

In this example, 1 is added to the value of `x`, and that new value is then assigned to `x`. It is a shorthand equivalent of the following statement:

```
x = x + 1
```

A variety of compound assignment operations can be performed using operators of this type. If the value of the variable on the left side of the operator has not been set, it is treated as zero. For a list of these operators and more information about them, see Assignment Operators in the Visual Basic Language Reference.

Lastly, the concatenation assignment operator is useful for adding a string to the end of already existing strings, as illustrated in this example:

```
Dim x As String = "My "
x &= "String"    ' x equals "My String".
```

If the variable on the left side of the concatenation assignment operator has not been assigned a value, it is treated as an empty string ("").

Widening and Narrowing Conversions

When assigning values, you must always assign a value to a variable of the appropriate type. Some numeric types can be converted to other numeric types. If **Option Strict** is **On**, all of the literals and variables in a numeric expression must either be the same data type (for example, **Integer**), or be types that are implicitly convertible to the widest (most precise) type. Visual Basic .NET implicitly converts Byte, Short, and Integer types as Long when they are assigned to a Long variable. This is called a widening conversion. Numeric type conversions in the following direction are widening: **Byte**, **Short**, **Integer**, **Long**, **Decimal**, **Single**, **Double**. An example of widening conversion is shown below:

```
Dim x As Double
Dim y As Integer = 6
Dim z As Integer = 23
x = y + z
```

Even though `y + z` returns a value that is type **Integer**, it can be implicitly converted to type **Double** and assigned to `x` because there is no possible loss of information in a conversion in that direction.

Conversions in the other direction are called narrowing conversions. These are conversions that can result in an overflow error at runtime. An example is shown below:

```
Dim x As Integer
Dim y As Double = 34.445
Dim z As Double = 22.12
x = y + z
' Since x is an Integer, it cannot accept the information on the right
' side of the decimal point. Conversion will lose information.
```

If **Option Strict** is **On**, the above example raises a compiler error. If **Option Strict** is **Off**, however, the conversion is performed implicitly, even though this implicit conversion may cause an error at runtime. For this reason, you should always use **Option Strict On**. For further information about widening and narrowing conversions, see Widening and Narrowing Conversions.

Though a widening conversion will never cause an overflow error, one can sometimes cause a loss of precision. For example, conversion of type **Decimal** to type **Single** is a widening conversion. But the **Decimal** type holds more significant digits than **Single**, so this conversion may cause the least significant digits to be lost. For this reason, all conversions should be handled carefully.

Statements Overview | Declaration Statements | Executable Statements | Assignment Operators | Widening and Narrowing Conversions

Declaration Statements

You use declaration statements to name and define procedures, variables, arrays, and constants. When you declare a procedure, variable, or constant, you also define its scope, depending on where you place the declaration and what keywords you use to declare it.

The following example contains three declarations.

```
Public Sub ApplyFormat()
   Const limit As Integer = 33
   Dim myWidget As Widget
   ' Insert code to implement the method.
End Sub
```

First, the **Public Sub** statement (with matching **End Sub** statement) declares a procedure named `ApplyFormat`. All the statements enclosed by the **Public Sub** and **End Sub** statements are executed whenever the `ApplyFormat` procedure is called or run.

Next, the **Const** statement declares the constant `limit`, specifying the **Integer** data type and a value of 33.

Finally, the **Dim** statement declares the variable `myWidget`. The data type is an object, in this case, a `Widget` object. You can declare a variable to be any object that is exposed in the application you are using. **Dim** statements are one type of statement used to declare variables. Other keywords used in declarations are **ReDim, Static, Public, Private, Protected,** and **Friend**.

A declaration statement reserves the memory needed to create a variable, but does not explicitly create it. You can explicitly create a variable and assign it a value at the same time by using the following syntax:

```
Dim x As Integer = 45   ' x is created and assigned the value 45.
```

If your variable is an object variable, you can explicitly create an instance of its class when you declare it by using the **New** keyword, as illustrated below:

```
Dim x As New System.Windows.Forms.Form()
```

See Also

Statements Overview | Assignment Statements | Executable Statements | Declaring Constants

Executable Statements

An executable statement initiates action by executing a method. It can loop or branch through blocks of code. Executable statements often contain mathematical or conditional operators.

The following example uses an **If...Then...Else** statement to execute different blocks of code based on the value of a variable. Within each block of code, a **For...Next** statement causes a loop to be executed a specified number of times.

```
Public Sub StartWidget(aWidget As Widget, clockwise As Boolean, _
   revolutions As Integer)
   Dim counter As Integer
   If clockwise = True Then
      For counter = 1 to revolutions
         aWidget.SpinClockwise
      Next counter
   Else
      For counter = 1 to revolutions
         aWidget.SpinCounterClockwise
      Next counter
   End If
End Sub
```

The **If...Then...Else** statement in the example checks the value of the variable `clockwise`. If the value is **True**, the `SpinClockwise` method of `aWidget` is invoked. If the value is **False**, then the `SpinCounterClockwise` method of `aWidget` is invoked. **If...Then...Else** statements end with **End If**.

The **For...Next** statements within each block cause the appropriate method to be invoked a number of times equal to the `revolutions` variable.

Procedures Overview

A *procedure* is a block of Visual Basic statements enclosed by a declaration statement and an **End** statement. All Visual Basic code is written within procedures.

A procedure is invoked from some other place in the code. When it is finished executing, it returns control to the code that invoked it; this code is known as the *calling code*. The calling code is a statement, or an expression within a statement, that specifies the procedure by name and transfers control to it.

Types of Procedures

Visual Basic uses several types of procedures:

- **Sub** procedures perform actions but do not return a value to the calling code.
- Event-handling procedures are **Sub** procedures that execute in response to an event triggered by user action or by an occurrence in a program.
- **Function** procedures return a value to the calling code.
- **Property** procedures return and assign values of properties on objects or modules.

Procedures and Structured Code

Every line of code in your application must be inside some procedure, such as `Main`, `Calculate`, or `Button1_Click`. If you subdivide large procedures into smaller ones, your application is more readable.

Procedures are useful for performing repeated or shared tasks, such as frequently used calculations, text and control manipulation, and database operations. You can call a procedure from many different places in your code, so you can use procedures as building blocks for your application.

Structuring your code with procedures gives you the following benefits:

- Procedures allow you to break your programs into discrete logical units. You can debug separate units more easily than you can an entire program without procedures.
- You can use procedures developed for one program in other programs, often with little or no modification.

See Also

Procedures | Sub Procedures | Function Procedures | Property Procedures | Procedure Arguments | Recursive Procedures | Procedure Overloading | Sub Statement

Sub Procedures

A **Sub** procedure is a series of Visual Basic statements enclosed by the **Sub** and **End Sub** statements. Each time the procedure is called, its statements are executed, starting with the first executable statement after the **Sub** statement and ending with the first **End Sub**, **Exit Sub**, or **Return** statement encountered.

A **Sub** procedure performs actions but does not return a value. It can take arguments, such as constants, variables, or expressions, that are passed to it by the calling code.

The syntax for declaring a **Sub** procedure is as follows:

```
[accessibility] Sub subname[(argumentlist)]
   ' Statements of the Sub procedure go here.
End Sub
```

The accessibility can be Public, Protected, Friend, **Protected Friend**, or Private.

You can define **Sub** procedures in modules, classes, and structures. They are **Public** by default, which means you can call them from anywhere in your application.

Argument Declaration

You declare each argument for a procedure the same way you declare a variable, specifying the argument name and data type. You can also specify the passing mechanism, and whether the argument is optional.

The syntax for each argument in the argument list is as follows:

```
[Optional] [ByVal|ByRef] [ParamArray] argumentname As datatype
```

If the argument is optional, you must also supply a default value in its declaration, as follows:

```
Optional [ByVal|ByRef] argumentname As datatype = defaultvalue
```

Calling Syntax

You invoke a **Sub** procedure explicitly with a stand-alone calling statement. You cannot call it by using its name within an expression. The calling statement must provide values for all arguments that are not optional, and it must enclose the argument list in parentheses. If no arguments are supplied, you can optionally omit the parentheses. The use of the **Call** keyword is optional also.

The syntax for a call to a **Sub** procedure is as follows:

```
[Call] subname[(argumentlist)]
```

The following **Sub** procedure tells the computer operator which task the application is about to perform, and also displays a time stamp. Instead of duplicating this code at the beginning of every task, the application simply calls `TellOperator` from various places. Each call passes a string in the `Task` argument that identifies the task being started.

```
Sub TellOperator(ByVal Task As String)
   Dim Stamp As Date      ' Stamp is local to TellOperator.
   Stamp = TimeOfDay()    ' Get current time for time stamp.
   ' Use MessageBox class of System.Windows.Forms namespace.
   MessageBox.Show("Starting " & Task & " at " & CStr(Stamp))
End Sub
```

A typical call to `TellOperator` is as follows:

```
Call TellOperator("file update")
```

See Also

Event-Handling Procedures

An event is an action or an occurrence — such as a mouse click or a credit limit exceeded — that is recognized by some object, and for which you can write code to respond. Events can occur as a result of a user action or a program calculation, or they can be triggered by the system. An event-handling procedure, or *event handler*, is the code you write to respond to a particular event.

Although an event handler is a **Sub** procedure, you usually do not call it in the same manner as other **Sub** procedures. When an object recognizes that an event has occurred, it invokes the event handler using the name corresponding to the event. This is known as *raising* the event, which the object does by executing the **RaiseEvent** statement.

For a discussion of writing event handlers, see Writing Event Handlers.

See Also

Procedures | Sub Procedures | Procedure Arguments | Events and Delegates | Events and Event Handlers | RaiseEvent Statement

Function Procedures

A **Function** procedure is a series of Visual Basic statements enclosed by the **Function** and **End Function** statements. Each time the procedure is called, its statements are executed, starting with the first executable statement after the **Function** statement and ending with the first **End Function**, **Exit Function**, or **Return** statement encountered.

A **Function** procedure is similar to a **Sub** procedure, but it also returns a value to the calling program. A **Function** procedure can take arguments passed to it by the calling code, such as constants, variables, or expressions.

The syntax for declaring a **Function** procedure is as follows:

```
[accessibility] Function functionname[(argumentlist)] As datatype
   ' Statements of the Function procedure.
End Function
```

The accessibility can be Public, Protected, Friend, **Protected Friend**, or Private.

You can define **Function** procedures in modules, classes, and structures. They are **Public** by default, which means you can call them from anywhere in your application.

You declare each argument the same as you do for a **Sub** procedure.

Return Values

The value a **Function** procedure sends back to the calling program is called its *return value*. The function returns the value in one of two ways:

- It assigns a value to its own function name in one or more statements of the procedure. Control is not returned to the calling program until an **Exit Function** or **End Function** statement is executed, as in the following example:

```
Function functionname[(argumentlist)] As datatype
   ' ...
   functionname = expression   'Control remains within the function.
   ' ...
End Function
```

- It uses the **Return** statement to specify the return value, and returns control immediately to the calling program, as in the following example:

```
Function functionname[(argumentlist)] As datatype
   ' ...
   Return expression   'Control is returned immediately.
   ' ...
End Function
```

The advantage of assigning the return value to the function name is that control does not return from the function until the program encounters an **Exit Function** or **End Function** statement. This allows you to assign a preliminary value and adjust it later if necessary.

If the function returns an array data type, you cannot access the individual elements of the array within the function. If you attempt to do this, the compiler interprets it as a call to the function. The following example generates compiler errors:

```
Function AllOnes(ByVal N As Integer) As Integer()
   Dim I As Integer    ' Singleton Integer, not Integer array.
   For I = 1 To N - 1    ' Assume N has a valid value.
      AllOnes(I) = 1    ' Compiler error: call with wrong data type.
   Next I
   Return AllOnes()    ' Compiler error: call with no argument.
End Function
```

Every **Function** procedure has a data type, just as every variable does. This data type is specified by the **As** clause in the **Function** statement, and it determines the type of the return value. The following sample declarations illustrate this:

```
Function Yesterday As Date
   ' ...
End Function
Function FindSqrt(ByVal Number As Single) As Single
   ' ...
End Function
```

Calling Syntax

You call a **Function** procedure by including its name and arguments either on the right side of an assignment statement or in an expression. The following sample calls illustrate this:

```
lvalue = functionname[(argumentlist)]
If ((functionname[(argumentlist)] / 3) <= expression) Then ...
```

The following **Function** procedure calculates the longest side, or hypotenuse, of a right triangle, given the values for the other two sides:

```
Function Hypotenuse (ByVal Side1 As Single, ByVal Side2 As Single) As Single
   Return Math.Sqrt((Side1 ^ 2) + (Side2 ^ 2))
End Function
```

Typical calls to `Hypotenuse` are as follows:

```
Dim TestLength, TestHypotenuse, X, Y, Area As Single
TestHypotenuse = Hypotenuse(TestLength, 10.7)
' Assume TriangleArea is a defined Function procedure — the
' returned value from Hypotenuse is used as an argument to TriangleArea.
Area = TriangleArea(X, Y, Hypotenuse(X, Y))
```

The common language runtime provides many functions, located in the **Microsoft.VisualBasic** namespace. These include such common functions as **Beep**, **MsgBox**, and **StrComp**. You call these functions the same way you call your own **Function** procedures.

When you call a **Function** procedure, you do not have to use its return value. If you do not, all the actions of the function are performed, but the return value is ignored. **MsgBox** is often called in this manner.

Property Procedures

A **Property** procedure is a series of Visual Basic statements that manipulate a custom property on a module, class, or structure. Property procedures are also known as *property accessors*.

A property differs from a public variable or a field in the following respects:

- You implement a property with executable code (its **Property** procedures), rather than with a single declaration statement.
- **Property** procedures are executed when the property value is set or retrieved. This allows a class to perform custom actions when client code accesses the property.
- A property does not have any storage location associated with its declaration. Although its **Property** procedures often define local variables and constants, these are usually not available to the code accessing the property. Therefore, while you can include a variable or a field as a member of a structure or array, you cannot do this with a property.
- You can define a property as read-only, write-only, or read/write. The default is read/write.

Visual Basic provides the following **Property** procedures:

- **Get** procedures return the value of a property; they are called when the property is accessed in an expression.
- **Set** procedures set a property to a value, including an object reference; they are called when a value is assigned to the property.

You usually define **Property** procedures in pairs, using the **Get** and **Set** keywords, but you can define either procedure alone if the property is read-only (**Get**) or write-only (**Set**).

Property Declaration

A property itself is defined by a block of code enclosed within the **Property** and **End Property** statements. Inside this block, each **Property** procedure appears as an internal block enclosed within a declaration statement (**Get** or **Set**) and an **End** statement. The syntax for declaring a property and its procedures is as follows:

```
[Default] [accessibility] Property propertyname[(argumentlist)] As datatype
Get
   ' ...
   Return expression   ' expression is returned as property's value.
End Get
Set [(ByVal newvalue As datatype)]
   ' ...
   lvalue = newvalue   ' newvalue is the new value to be assigned.
End Set
End Property
```

The accessibility can be Public, Protected, Friend, **Protected Friend**, or Private.

You can define properties in classes, structures, and modules. Properties are **Public** by default, which means you can call them from anywhere in your application.

Argument Declaration

You declare each argument the same as for a **Function** or **Sub** procedure, except that the passing mechanism must be by value.

The syntax for each argument in the argument list is as follows:

```
[Optional] ByVal [ParamArray] argumentname As datatype
```

If the argument is optional, you must also supply a default value in its declaration, as follows:

```
Optional ByVal argumentname As datatype = defaultvalue
```

In a **Get** procedure, the return value is supplied to the calling expression as the value of the property.

In a **Set** procedure, the new property value is passed through the argument of the **Set** statement. If you declare an explicit argument, you must declare it as the same data type as the property. If you do not declare an argument, the compiler uses the

implicit argument ***Value*** to represent the new value to be assigned to the property.

Calling Syntax

A **Property** procedure is invoked implicitly by code that makes reference to the property. The code uses the name of the property the same way it would use the name of a variable, except that it must provide values for all arguments that are not optional, and it must enclose the argument list in parentheses. If no arguments are supplied, you can optionally omit the parentheses.

The syntax for an implicit call to a **Set Property** procedure is as follows:

```
propertyname[(argumentlist)] = expression
```

The following sample calls show allowable calling syntax for a **Get Property** procedure:

```
lvalue = propertyname[(argumentlist)]
Do While (propertyname[(argumentlist)] > expression)
```

> **Note** A property's data type and access are defined in the **Property** statement, not in the **Property** procedures. A property can have only one data type and one accessibility. For example, you cannot define a property to set a **Decimal** value, but get a **Double** value. Similarly, you cannot define a **Private Set** and a **Public Get** on the same property. To achieve this functionality, you can define a **Public ReadOnly** property and a **Private** setting method separate from the property.

Procedure Arguments

In most cases, a procedure needs some information about the circumstances in which it has just been called. A procedure that performs repeated or shared tasks uses different information for each call. This information consists of variables, constants, and expressions that are passed to the procedure when it is called. Each value passed to a procedure is called an *argument*.

Argument Data Type Declaration

You declare a data type for an argument by using the **As** clause in its declaration. For example, the following function accepts a string and an integer:

```
Function Appointment(ByVal Day As String, ByVal Hour As Integer) As String
   ' Code to return any appointment for the given day and time.
End Function
```

If the type checking switch (Option Strict Statement) is off, the **As** clause is optional, except that if any one argument uses it, all arguments must use it. If type checking is on, the **As** clause is required for all procedure arguments.

If you intend to pass different data types to a particular argument, such as **Byte** to **Integer** or late bound classes to **Object**, you must have **Option Strict Off**.

Argument Passing ByVal and ByRef

In Visual Basic, you can pass an argument to a procedure *by value* or *by reference* by specifying the **ByVal** or **ByRef** keywords, respectively. Passing an argument by value means the procedure cannot modify the contents of the variable element in the calling code underlying the argument. Passing by reference allows the procedure to modify the contents in the same way that the calling code itself can.

Passing arguments by value and by reference is not the same distinction as the classification of data types into value types and reference types. However, the two categories do interact.

Variable and Nonvariable Arguments

The programming element underlying an argument can be either a variable element, capable of having its value changed, or a nonvariable element. The following table lists variable and nonvariable elements.

Variable elements	Nonvariable elements
Declared variables, including object variables	Constants
Fields (of classes)	Literals
Array elements	Enumerations
Structure elements	Expressions

Nonvariable arguments are never modified in the calling code, even if they are passed by reference. The called procedure might modify its copy of such an argument, but that modification does not affect the underlying element in the calling code.

In This Section

Argument Passing ByVal
Describes passing arguments by value, which means the procedure cannot modify the variable itself.
Argument Passing ByRef
Describes passing arguments by reference, which means the procedure can modify the variable itself.
Argument Passing Mechanism
Summarizes the interaction between the element's data type and the passing mechanism.

Related Sections

Procedures
Provides links to topics about Visual Basic procedures, including information on the different procedure types and how they are called.

Argument Passing ByVal

If you pass a variable argument by value using the **ByVal** keyword, the procedure cannot modify the variable itself. However, if the argument is a reference type, you can modify the members of the object to which it points, even though you cannot replace the object itself. In particular, you can modify the members of the object. For example, if the argument is an array variable, you cannot assign a new array to it, but you can change one or more of its elements. The changed elements are reflected in the underlying array variable in the calling code.

The following example shows two subroutines that take an array variable by value and operate on its elements. `Increase` simply adds one to each element. `Replace` assigns a new array to the argument array `A()` and then adds one to each element. However, the reassignment does not affect the underlying array variable in the calling code.

```
Public Sub Increase(ByVal A() As Long)
   Dim J As Integer
   For J = 0 To UBound(A)
      A(J) = A(J) + 1
   Next J
End Sub
   ' ...
Public Sub Replace(ByVal A() As Long)
   Dim J As Integer
   Dim K() As Long = {100, 200, 300}
   A = K
   For J = 0 To UBound(A)
      A(J) = A(J) + 1
   Next J
End Sub
 ' ...
Dim N() As Long = {10, 20, 30, 40}
Increase(N)
MsgBox("After Increase(N): " & _
             CStr(N(0)) & CStr(N(1)) & CStr(N(2)) & CStr(N(3)))
' The element values of N() are now 11, 21, 31, and 41. Because N is a
' reference type, Replace could change its members.
Replace(N)
MsgBox("After Replace(N): " & _
             CStr(N(0)) & CStr(N(1)) & CStr(N(2)) & CStr(N(3)))
' The element values of N() are still 11, 21, 31, and 41. Because N was
' passed ByVal, Replace could not modify the variable N by assigning a
' new array to it. When Replace created the new array instance K and
' assigned it to the local variable A, it lost the reference to N()
' passed in by the calling code. When it changed the members of A(),
' only the local array K() was affected.
```

See Also

Argument Passing ByRef | Argument Passing Mechanism | Argument Passing by Position and by Name | ByVal | ByRef

Argument Passing ByRef

If you pass a variable argument by reference using the **ByRef** keyword, the procedure can modify the variable itself. In particular, if the argument is an object variable, you can assign a new object to it. This reassignment also affects the object variable in the calling program.

In the example provided in Argument Passing ByVal, if the `Replace` subroutine had instead taken the argument array by reference, the new array `K()` would have been assigned to the array variable `N` in the calling code. The results for `N()` would then have been as follows:

```
MsgBox("After Replace(N) taking A() argument ByRef: " & _
             CStr(N(0)) & CStr(N(1)) & CStr(N(2)) & CStr(N(3)))
' The element values of N() are now 101, 201, and 301. Because N was
' passed ByRef, Replace could modify the variable N and assign a new
' array to it. Because N is a reference type, Replace could also change
' its members.
```

See Also

Argument Passing Mechanism | Argument Passing by Position and by Name | ByVal | ByRef

Argument Passing Mechanism

When a nonvariable element is passed as an argument, the procedure can never modify it in the calling code, whether it is passed **ByVal** or **ByRef**. For a variable element, the following table summarizes the interaction between the element's data type and the passing mechanism.

Element type	Passed ByVal	Passed ByRef
Value type (contains only a value)	The procedure cannot change the variable or any of its members.	The procedure can change the variable and its members.
Reference type (contains a pointer to a class or structure instance)	The procedure cannot change the variable but can change members of the instance to which it points.	The procedure can change the variable and members of the instance to which it points.

Determination of the Passing Mechanism

The procedure declaration determines the passing mechanism. The calling code cannot override a **ByVal** mechanism, but if an argument is declared with **ByRef**, the calling code can force the mechanism to pass by value by enclosing the argument name in parentheses in the call. The following example illustrates this:

```
Sub DoSomething(ByRef InString As String)
   ' Code that makes changes to InString.
End Sub
' ...
Dim Str As String = "Cannot be replaced if passed ByVal"
Call DoSomething((Str))   ' Pass Str ByVal even though declared ByRef.
' The parentheses around Str protect it from change.
```

The default in Visual Basic is to pass arguments by value. You can make your code easier to read by using the **ByVal** keyword, as in the following example:

```
Sub PostAccounts(ByVal AcctNum As Integer)
   ' Code to post accounts.
End Sub
```

When you pass a variable by reference, you must use the **ByRef** keyword to specify this mechanism. The preceding example can be extended with a second argument as follows:

```
Sub PostAccount(ByVal AcctNum As Integer, ByRef RunningTotal As Single)
   ' Code to post account for AcctNum and change value of RunningTotal.
End Sub
```

It is good programming practice to include either the **ByVal** or **ByRef** keyword with every declared argument.

Choice of the Passing Mechanism

In choosing between the two passing mechanisms, the most important criterion is the exposure of calling variables to change. The advantage of passing an argument **ByRef** is that the procedure can return a value to the calling code through that argument. The advantage of passing an argument **ByVal** is that it protects a variable from being changed by the procedure.

Although the passing mechanism can also affect the performance of your code, the difference is usually insignificant. One exception to this is a value type passed **ByVal**. In this case, Visual Basic copies the entire data contents of the argument. Therefore, for a large value type such as a structure, it is more efficient to pass it **ByRef**.

For reference types, only the four-byte pointer to the data is copied. Therefore, you can pass arguments of type **String** or **Object** **ByVal** without harming performance.

See Also

Argument Passing ByVal | Argument Passing ByRef | Argument Passing by Position and by Name | Procedures | Procedure Arguments | Argument Data Type Declaration | Optional Arguments | Parameter Arrays | Value Types and Reference Types | ByVal | ByRef

Argument Passing by Position and by Name

When you call a **Sub** or **Function** procedure, you can pass arguments *by position* — that is, in the order in which they appear in the procedure's definition — or you can pass them *by name*, without regard to position.

When you pass an argument by name, you specify the argument's declared name followed by a colon and an equal sign (**:=**), followed by the argument value. You can supply named arguments in any order.

For example, the following **Sub** procedure takes three arguments:

```
Sub StudentInfo(ByVal Name As String, Optional ByVal Age As Short = 0, _
                        Optional ByVal Birth As Date = #1/1/2000#)
   Debug.WriteLine("Name = " & Name & "; age = " & CStr(Age) & _
                   "; birth date = " & CStr(Birth))
End Sub
```

When you call this procedure, you can supply the arguments by position, by name, or by using a mixture of both.

Passing Arguments by Position

You can call the procedure `StudentInfo` with its arguments passed by position and delimited by commas, as shown in the following example:

```
StudentInfo("Mary", 19, #9/21/1981#)
```

If you omit an optional argument in a positional argument list, you must hold its place with a comma. The following example calls `StudentInfo` without the `Age` argument:

```
StudentInfo("Mary", , #9/21/1981#)
```

Passing Arguments by Name

Alternatively, you can call `StudentInfo` with the arguments passed by name, also delimited by commas, as shown in the following example:

```
StudentInfo(Age:=19, Birth:=#9/21/1981#, Name:="Mary")
```

Mixing Arguments by Position and by Name

You can supply arguments both by position and by name in a single procedure call, as shown in the following example:

```
StudentInfo("Mary", Birth:=#9/21/1981#)
```

In the preceding example, no extra comma is necessary to hold the place of the omitted `Age` argument, since `Birth` is passed by name.

If you supply arguments both by position and by name, the positional arguments must all come first. Once you supply an argument by name, the remaining arguments must all be by name.

Supplying Optional Arguments by Name

Passing arguments by name is especially useful when you call a procedure that has more than one optional argument. If you supply arguments by name, you do not have to use consecutive commas to denote missing positional arguments. Passing arguments by name also makes it easier to keep track of which arguments you are passing and which ones you are omitting.

Restrictions on Supplying Arguments by Name

You cannot pass arguments by name to avoid entering required arguments. You can omit only the optional arguments.

You cannot pass a parameter array by name. This is because when you call the procedure, you supply an indefinite number of

comma-separated arguments for the parameter array, and the compiler cannot associate more than one argument with a single name.

See Also

Procedures | Procedure Arguments | Argument Data Type Declaration | Argument Passing ByVal and ByRef | Optional Arguments | Parameter Arrays | ByVal | ByRef | Optional | ParamArray

Optional Arguments

You can specify that a procedure argument is optional and does not have to be supplied when the procedure is called. *Optional arguments* are indicated by the **Optional** keyword in the procedure definition. The following rules apply:

- Every optional argument in the procedure definition must specify a default value.
- The default value for an optional argument must be a constant expression.
- Every argument following an optional argument in the procedure definition must also be optional.

The following syntax shows a procedure declaration with an optional argument:

```
    Sub subname(ByVal arg1 As type1, Optional ByVal arg2 As type2 = default)
```

Calling Procedures with Optional Arguments

When you call a procedure with an optional argument, you can choose whether to supply the argument. If you do not, the procedure uses the default value declared for that argument.

When you omit one or more optional arguments in the argument list, you use successive commas to mark their positions. The following example call supplies the first and fourth arguments but not the second or third:

```
    Call subname(arg1, , , arg4)   ' Leaves out arg2 and arg3.
```

Determining Whether an Optional Argument Is Present

A procedure cannot detect at run time whether a given argument has been omitted or the calling code has explicitly supplied the default value. If you need to make this distinction, you can set an unlikely value as the default. The following procedure includes the optional argument `Office`, and tests for its default value, `QJZ`, to see if it has been omitted:

```
Sub Notify(ByVal Company As String, Optional ByVal Office As String = "QJZ")
   If Office = "QJZ" Then
      Debug.WriteLine("Office not supplied -- notifying Headquarters")
      Office = "Headquarters"
   End If
   ' Code to notify headquarters or specified office.
End Sub
```

If the optional argument is a reference type such as a **String**, you can use **Nothing** as the default value, provided this is not an expected value for the argument.

Another way to define a procedure with optional arguments is to use overloading. If you have one optional argument, you can define two overloaded versions of the procedure, one with the argument and one without it. This approach becomes more complicated as the number of optional arguments increases. However, its advantage is that you can be absolutely sure whether the calling program supplied each optional argument.

See Also

Procedures | Procedure Arguments | Argument Data Type Declaration | Argument Passing ByVal and ByRef | Argument Passing by Position and by Name | Parameter Arrays | Procedure Overloading | Considerations in Overloading Procedures | Optional

Parameter Arrays

Usually, you cannot call a procedure with more arguments than the procedure declaration specifies. When you need an indefinite number of arguments, you can declare a *parameter array*, which allows a procedure to accept an array of values for an argument. You do not have to know the number of elements in the parameter array when you define the procedure. The array size is determined individually by each call to the procedure.

You use the **ParamArray** keyword to denote a parameter array. The following rules apply:

- A procedure can have only one parameter array, and it must be the last argument in the procedure definition.
- The parameter array must be passed by value. It is good programming practice to explicitly include the **ByVal** keyword in the procedure definition.
- The code within the procedure must treat the parameter array as a one-dimensional array, each element of which is the same data type as the **ParamArray** data type.
- The parameter array is automatically optional. Its default value is an empty one-dimensional array of the parameter array's element type.
- All arguments preceding the parameter array must be required. The parameter array must be the only optional argument.

When you call a procedure with a parameter array argument, you can pass any of the following for the parameter array:

- Nothing — that is, you can omit the **ParamArray** argument. In this case, an empty array is passed to the procedure. You can also pass the **Nothing** keyword, with the same effect.
- A list of an indefinite number of arguments, separated by commas. The data type of each argument must be implicitly convertible to the **ParamArray** element type.
- An array with the same element type as the parameter array.

The following example shows how you can define a procedure with a parameter array:

```
Sub StudentScores(ByVal Name As String, ByVal ParamArray Scores() As String)
   Dim I As Integer
   Debug.WriteLine("Scores for " & Name & ":")
   ' Use UBound function to determine largest subscript of array.
   For I = 0 To UBound(Scores)
      Debug.WriteLine("Score " & I & ": " & Scores(I))
   Next I
End Sub
```

The following examples show typical calls to `StudentScores`:

```
StudentScores("Anne", "10", "26", "32", "15", "22", "24", "16")
StudentScores("Mary", "High", "Low", "Average", "High")
Dim JohnScores() As String = {"35", "Absent", "21", "30"}
StudentScores("John", JohnScores)
```

Recursive Procedures

A *recursive* procedure is one that calls itself. For example, the following procedure uses recursion to calculate the factorial of its original argument:

```
Function Factorial(ByVal N As Integer) As Integer
   If N <= 1 Then      ' Reached end of recursive calls.
      Return 1         ' N = 0 or 1, so climb back out of calls.
   Else                ' N > 1, so call Factorial again.
      Return Factorial(N - 1) * N
   End If
End Function
```

> **Note** When a **Function** procedure calls itself recursively, the procedure name must be followed by parentheses, even if there is no argument list. Otherwise, the function name is taken as representing the return value of the function.

Programs have a limited amount of space for variables. Each time a procedure calls itself, more of that space is used. If this process continues indefinitely, it eventually causes a stack space error. The cause may be less obvious if two procedures call each other indefinitely, or if a condition that limits the recursion is never met.

You should test your recursive procedure to make sure it does not call itself indefinitely, or so many times that you run out of memory. You can often substitute loops for recursion.

Procedure Overloading

Overloading a procedure means defining it in multiple versions, using the same name but different argument lists. The purpose of overloading is to define several closely related versions of a procedure without having to differentiate them by name. You do this by varying the argument list.

In This Section

Rules of Procedure Overloading
Discusses the requirements of procedure overloading, including the ways in which overloaded versions must differ from each other (in number, order, or data types of arguments).

Considerations in Overloading Procedures
Discusses restrictions on overloading optional arguments, implicit overloads for **ParamArray** arguments, and typeless programming as an alternative to overloading.

Overload Resolution
Describes the steps the Visual Basic compiler takes when, encountering a call to a procedure that is defined in several overloaded versions, it decides which overload to call.

Related Sections

Procedures
Provides links to topics about Visual Basic procedures, including information on the different procedure types and how they are called.

Rules of Procedure Overloading

When you overload a procedure, the following rules apply:

- Each overloaded version must use the same procedure name.
- Each overloaded version must differ from all other overloaded versions in at least one of the following respects:
    - Number of arguments
    - Order of the arguments
    - Data types of the arguments

The compiler uses the procedure name and the argument list to check that the call correctly matches the definition. These items are collectively called the *signature* of the procedure.

You cannot overload a procedure without varying the argument list. In particular, you cannot overload a procedure by varying only one or more of the following items:

- Procedure modifier keywords, such as **Public**, **Shared**, and **Static**
- Argument names
- Argument modifier keywords, such as **ByRef** and **Optional**
- The data type of the return value

The items in the preceding list are not part of the signature.

> **Note** If you intend to pass a late-bound object variable to an overloaded procedure, you must declare the appropriate argument as **Object**.

Multiple Versions of a Procedure

Suppose you are writing a **Sub** procedure to post a transaction against a customer's balance, and you want to be able to refer to the customer either by name or by account number. To accommodate this, you can define two different **Sub** procedures, as in the following example:

```
Sub PostName(ByVal CustName As String, ByVal Amount As Single)
Sub PostAcct(ByVal CustAcct As Integer, ByVal Amount As Single)
```

An alternative is to overload a single procedure name. You can use the **Overloads** keyword to define a version of the procedure for each argument list, as follows:

```
Overloads Sub Post(ByVal CustName As String, ByVal Amount As Single)
   ' Code to access customer record by customer name.
End Sub
Overloads Sub Post(ByVal CustAcct As Integer, ByVal Amount As Single)
   ' Code to access customer record by account number.
End Sub
```

If you also wanted to accept a transaction amount in either **Decimal** or **Single**, you could further overload `Post` to allow for this variation. If you did this to each of the overloads in the preceding example, you would have four **Sub** procedures, all with the same name but with four different argument lists.

The advantage of overloading a procedure is in the flexibility of the call. To use the `Post` procedure declared in the preceding example, the calling code can obtain the customer identification as either a **String** or an **Integer**, and then call the same procedure in either case. The following example illustrates this:

```
Imports MSVB = Microsoft.VisualBasic   ' Namespace for InputBox.
Dim Customer As String       ' Customer's name.
Dim AccountNum As Integer    ' Customer's account number.
Dim Amount As Single
' ...
Customer = MSVB.Interaction.InputBox("Enter customer name or number")
Amount = MSVB.Interaction.InputBox("Enter transaction amount")
Try
AccountNum = CInt(Customer)   ' See if an integer was entered.
```

```
Post(AccountNum, Amount)   ' Post transaction against account number.
Catch
Post(Customer, Amount)      ' Post transaction against customer name.
End Try
```

See Also

Considerations in Overloading Procedures | Overload Resolution | Overloads

Considerations in Overloading Procedures

The following rules apply to overloading procedures:

- You must differentiate any two versions of a procedure by their argument lists.
- You cannot use anything other than the argument list to differentiate versions. For example, you cannot have two overloads that differ only in their return types.
- However, versions that are properly differentiated by their argument lists can have different return types or different argument modifiers.
- You can overload a **Function** procedure with a **Sub** procedure, and vice versa, provided they have different argument lists.
- You can overload a method or a property on a class you are defining. You do this the same way you overload procedures.
- However, you cannot define a method and a property with the same name in the same class. In other words, you cannot overload a method with a property, or vice versa.

Restrictions on Overloading Optional Arguments

A procedure with an optional argument is equivalent to two overloaded procedures, one with the optional argument and one without it. Because of this, you cannot overload such a procedure with an argument list corresponding to either of these. The following declarations illustrate this:

```
Overloads Sub Q(ByVal B As Byte, Optional ByVal J As Long = 6)
' The preceding definition is equivalent to the following two:
'                   Overloads Sub Q(ByVal B As Byte)
'                   Overloads Sub Q(ByVal B As Byte, ByVal J As Long)
' Therefore, the following overload is not valid:
Overloads Sub Q(ByVal C As Byte, ByVal K As Long)   ' Signature in use.
' The following overload uses a different argument list and is valid:
Overloads Sub Q(ByVal B As Byte, ByVal J As Long, ByVal S As Single)
```

For a procedure with more than one optional argument, there is a set of invalid overloads, arrived at by logic similar to that in the preceding example.

Implicit Overloads for a ParamArray Argument

The compiler considers a procedure with a **ParamArray** argument to have an infinite number of overloads, differing from each other in what is passed to the parameter array, as follows:

- One overload passing a one-dimensional array of the **ParamArray** element type
- One overload passing no argument to the **ParamArray**
- For every positive integer, one overload passing that number of arguments, each of the **ParamArray** element type

The following declarations illustrate these implicit overloads:

```
Sub P(ByVal D As Date, ByVal ParamArray C() As Char)
' The preceding definition is equivalent to the following overloads:
'    Overloads Sub P(ByVal D As Date, ByVal C() As Char)
'    Overloads Sub P(ByVal D As Date)
'    Overloads Sub P(ByVal D As Date, ByVal C As Char)
'    Overloads Sub P(ByVal D As Date, ByVal C1 As Char, ByVal C2 As Char)
' And so on, with an additional Char argument in each successive overload.
```

Typeless Programming as an Alternative to Overloading

If you want to allow different data types to be passed to an argument, an alternative approach is typeless programming; that is, turning **Option Explicit** off and not declaring the argument's data type. However, this approach has the following disadvantages compared to overloading:

- Typeless programming produces less efficient execution code.
- The procedure must test for every data type it anticipates being passed.
- The compiler cannot signal an error if the calling code passes a data type that the procedure does not support.

Overload Resolution

When the Visual Basic compiler encounters a call to a procedure that is defined in several overloaded versions, the compiler must decide which of the overloads to call. It does this by performing the following steps:

1. It eliminates any overload that defines a different number of arguments than are supplied in the call.
2. It eliminates any overload for which the data types of the calling arguments cannot be converted to the types defined in the overload.
3. It eliminates any overload that requires a narrowing conversion from the calling argument types to the defined argument types. This is true whether the type checking switch (Option Strict Statement) is on or off.
4. It considers the remaining overloads in pairs. For each pair, it compares the data types of the defined arguments. If the types in one of the overloads all widen to the corresponding types in the other, the compiler eliminates the latter. That is, it retains the overload that calls for the least amount of widening.
5. It continues considering overloads in pairs until only one overload remains, and it resolves the call to that overload. If the compiler cannot reduce the overloads to a single candidate, it generates an error.

The following example illustrates this overload resolution process.

```
Overloads Sub Z(ByVal X As Byte, ByVal Y As Double)      ' Overload 1.
Overloads Sub Z(ByVal X As Short, ByVal Y As Single)     ' Overload 2.
Overloads Sub Z(ByVal X As Integer, ByVal Y As Single)   ' Overload 3.
' ...
Dim R, S As Short
Call Z(R, S)   ' Calls overload 2 (less widening than overload 3).
' ...
Dim B As Byte, S As Short
Call Z(B, S)   ' Generates compiler error (two candidates).
```

In the first call, `Overload 1` is eliminated because the type of the first calling argument (**Short**) narrows to the corresponding defined type (**Byte**). `Overload 3` is eliminated because each argument type in `Overload 2` (**Short** and **Single**) widens to the corresponding type in `Overload 3` (**Integer** and **Single**). `Overload 2` requires less widening, so the compiler uses it for the call.

In the second call, none of the overloads can be eliminated because of narrowing. `Overload 3` is eliminated for the same reason as in the first call, because `Overload 2` can be called with less widening of the argument types. However, the compiler cannot resolve between `Overload 1` and `Overload 2`. Each has one defined argument type that widens to the corresponding type in the other (**Byte** to **Short**, but **Single** to **Double**). The compiler therefore generates an overload resolution error.

Overloaded Optional and ParamArray Arguments

If two overloads have identical signatures except that the last argument is declared **Optional** in one and **ParamArray** in the other, the compiler resolves a call as follows:

If the call supplies the last argument as	The compiler resolves the call to the overload declaring the last argument as
No value (argument omitted)	**Optional**
A single value	**Optional**
Two or more values in a comma-separated list	**ParamArray**
An array of any length (including an empty array)	**ParamArray**

Control Flow

Left unregulated, a program proceeds through its statements from beginning to end. Some very simple programs can be written with only this unidirectional flow. However, most of the power and utility of any programming language comes from the ability to change execution order with control statements and loops.

Control-flow statements allow you to regulate the flow of your program's execution. Using control statements, you can write Visual Basic code that makes decisions and repeats actions. Another useful statement, **With...End With**, lets you execute a series of statements without having to requalify an object.

Provides links to language reference topics on this subject.

Decision Structures

Visual Basic allows you to test conditions and perform different operations depending on the results of that test. You can test for a condition being true or false, for various values of an expression, or for various exceptions generated when you execute a series of statements. The decision statements supported by Visual Basic include:

- **If...Then**
- **If...Then...Else**
- **Select...Case**
- **Try...Catch...Finally**

In This Section

If...Then...Else Statements
Discusses testing one or more **Boolean** conditions.
Select...Case Statements
Covers testing for different values of the same expression.
Try...Catch...Finally Statements
Explains testing for different exceptions generated by your code.

With...End With Statements
Explains how to execute several statements on the same object.
Nested Control Statements
Describes control-flow statements inside other control-flow statements.
Exit Statement
Discusses how to transfer control directly out of a control-flow statement.

If...Then...Else Statements

You can use **If...Then...Else** statements to execute a specific statement or block of statements depending on the **Boolean** value of a condition. The condition usually results from a comparison of two values, but it can be any expression that evaluates to a **Boolean** value (**True** or **False**). This includes values of other data types, such as numeric types, that have been converted to **Boolean**.

Executing Statements if a Condition Is True

To execute only one statement when a condition is **True**, you can use the single-line syntax of **If...Then...Else**, omitting the **Else** and **End If** statements, as in the following example:

```
Sub FixDate()
   Dim MyDate As Date = #2/13/1973#
   If MyDate < Now Then MyDate = Now
End Sub
```

To execute more than one line of code when the condition is **True**, you use multiple-line syntax, which includes the **End If** statement. If you have no code to run when the condition is **False**, you omit the **Else** statement, as the following example shows:

```
Dim AlertLabel As New System.Windows.Forms.Label
   ' ...
Sub AlertUser(ByVal Value As Long)
   If Value = 0 Then
     AlertLabel.ForeColor = Color.Red
     AlertLabel.Font = New Font(AlertLabel.Font, _
                                FontStyle.Bold Or FontStyle.Italic)
   End If
End Sub
```

Executing Some Statements if a Condition Is True and Others if It Is False

You can use **If...Then...Else** with the **Else** statement to define two blocks of executable statements. One block is executed if the condition is **True**, the other if it is **False**.

```
Dim AlertLabel As New System.Windows.Forms.Label
   ' ...
Sub AlertUser(ByVal Value As Long)
   If Value = 0 Then
     AlertLabel.ForeColor = Color.Red
     AlertLabel.Font = New Font(AlertLabel.Font, _
                                FontStyle.Bold Or FontStyle.Italic)
   Else
     AlertLabel.Forecolor = Color.Black
     AlertLabel.Font = New Font(AlertLabel.Font, _
                                FontStyle.Regular)
   End If
End Sub
```

Testing Additional Conditions if the First Condition Is False

You can add one or more **ElseIf** statements to **If...Then...Else** to test additional conditions if the first condition is **False**. For example, the following **Function** procedure computes a payroll bonus based on performance rating. The statement following the **Else** statement runs only if the conditions in all of the **If** and **ElseIf** statements are **False**.

```
Function Bonus(ByVal Performance As Integer, ByVal Salary As Decimal) _
              As Decimal
   If Performance = 1 Then
     Return Salary * 0.1
   ElseIf Performance = 2 Then
     Return Salary * 0.09
```

```
    ElseIf Performance = 3 Then
      Return Salary * 0.07
    Else
      Return 0
    End If
  End Function
```

Visual Basic tests the conditions in the order they appear in the **If...Then...Else** statements tests until it encounters a **True** condition or an **Else** statement, at which point it executes the corresponding statement block. Execution then branches to the end of the **If...Then...Else** block.

You can have any number of **ElseIf** statements, or none at all. You can include or omit an **Else** statement regardless of whether you have **ElseIf** statements.

If...Then...Else statements can be nested to as many levels as you need. However, for readability, you might want to use **Select...Case** statements rather than multiple levels of nested **If...Then...Else** statements or many **ElseIf** statements.

See Also

Loop Structures | Nested Control Statements | If...Then...Else Statements (Language Reference) | Select...Case Statements | Try...Catch...Finally Statements | Boolean Data Type | ElseIf

Select...Case Statements

When you are comparing the same expression to several different values, you can use the **Select...Case** statements as an alternative to the **If...Then...Else** statements. Whereas the **If** and **ElseIf** statements can evaluate a different expression in each statement, the **Select** statement evaluates a single expression only once and uses it for every comparison.

Visual Basic compares the value of the expression to the values in the **Case** statements in the order they appear in the **Select...Case** block. If it finds a match or a **Case Else** statement, it executes the corresponding statement block. In any case, it then executes the code following the **End Select** statement.

You can have any number of **Case** statements, and you can include or omit a **Case Else** statement.

In the following example, **Select...Case** is used to evaluate the performance rating that is passed to the **Function** procedure. Note that each **Case** statement can contain more than one value, a range of values, or a combination of values and comparison operators. When a **Case** statement contains more than one value, the **Case** block is executed if any of the values match the value of the **Select** statement expression.

```
Function Bonus(ByVal Performance As Integer, ByVal Salary As Decimal) _
      As Decimal
   Select Performance
     Case 1   ' Performance is 1.
        Return Salary * 0.1
     Case 2, 3   ' Performance is 2 or 3.
        Return Salary * 0.09
     Case 5 To 7   ' Performance is 5, 6, or 7.
        Return Salary * 0.07
     Case 4, 8 To 10   ' Performance is 4, 8, 9, or 10.
        Return Salary * 0.05
     Case Is < 15   ' Performance is 11, 12, 13, or 14.
        Return 100
     Case Else   ' Performance is < 1 or > 14.
        Return 0
   End Select
End Function
```

Loop Structures | Nested Control Statements | Select...Case Statements (Language Reference) | If...Then...Else Statements | Try...Catch...Finally Statements | Exit Statement

Try...Catch...Finally Statements

You can use the **Try...Catch...Finally** statements for structured exception handling. This allows you to execute a particular block of statements if a specified exception occurs while your code is running. When this happens, the code is said to *throw* the exception, and you *catch* it with the appropriate **Catch** statement.

Execution enters the **Try...Catch...Finally** block with the statement block following the **Try** statement. If Visual Basic completes this block without an exception being generated, it looks for the optional **Finally** statement at the end. If you have supplied the **Finally** statement, Visual Basic executes the statement block following it. In any case, control is then transferred to the statement following the **End Try** statement.

If an exception occurs, Visual Basic examines the **Catch** statements in the order they appear within **Try...Catch...Finally**. If it finds a **Catch** statement that handles the generated exception, it executes the corresponding statement block. When it has finished executing the **Catch** block, it executes the **Finally** block if it is present. Execution then proceeds to the statement following the **End Try** statement.

A **Catch** statement handles an exception that is of the same type as the type declared in the **Catch** statement, or of a type derived from it. If you supply a **Catch** statement that does not specify an exception type, it handles any exception derived from the **Exception** class. If such a statement is the last **Catch** statement, it can catch any exception that you did not handle in the preceding **Catch** blocks.

A **Catch** statement, whether or not it specifies an exception type, can optionally include the **When** clause. **When** is followed by an expression that must be convertible to **Boolean**. The exception is handled only if it is of the right type and the **When** expression evaluates to **True**, as in the following example:

```
Catch Exc As System.NotSupportedException When SupportCheck >= 1
```

If you supply the optional **Finally** statement, the corresponding statement block is always the last code to be executed just before control leaves **Try...Catch...Finally**. This is true even if an unhandled exception occurs, or if you execute an **Exit Try** statement.

You can have any number of **Catch** statements, and you can include or omit a **Finally** statement. However, you must have at least one **Catch** statement or a **Finally** statement.

You cannot branch out of a **Try** block, into a **Catch** block, or into or out of a **Finally** block. You can branch from a **Catch** block into the **Try** block associated with that **Catch**. For example, if one **Try...Catch...Finally** construction is nested within another, a **Catch** block can branch into the **Try** block at its own nesting level, but not into any other **Try** block.

In the following example, **Try...Catch...Finally** attempts to calculate the date and time exactly 100 years from the value provided in the **Object** variable `GivenDate`:

```
Dim GivenDate As Object   ' Should contain date/time information.
Dim NextCentury As Date
Try
   NextCentury = DateAdd("yyyy", 100, GivenDate)
   Catch ThisExcep As System.ArgumentException
   ' At least one argument has an invalid value.
   Catch ThisExcep As ArgumentOutOfRangeException
   ' The result is later than December 31, 9999.
   Catch ThisExcep As InvalidCastException
   ' GivenDate cannot be interpreted As a date/time.
   Catch
   ' An unforeseen exception has occurred.
   Finally
   ' This block is always executed before leaving.
End Try
```

The exceptions that you can anticipate from the **DateAdd** function can be handled in the first three **Catch** blocks, and you can deal with any unexpected exception in the last **Catch** block. No matter what happens, the **Finally** block is always the last code to be executed before leaving **Try...Catch...Finally**.

If `ThisExcep` does not appear in a declaration statement such as **Dim**, the **Catch** statement with the **As** clause serves as a declaration of the exception variable.

Loop Structures

Loop structures allow you to execute one or more lines of code repetitively. You can repeat the statements until a condition is true, until a condition is false, a specified number of times, or once for each object in a collection. The loop structures supported by Visual Basic include:

- **While**
- **Do...Loop**
- **For...Next**
- **For Each...Next**

In This Section

While Statement
Describes how to execute a block of statements while a condition is true.
Do...Loop Statements
Describes how to execute a block of statements until a condition is satisfied.
For...Next Statements
Describes how to execute a block of statements a specified number of times.
For Each...Next Statements
Describes how to execute a block of statements for each element in a collection.
Faster For...Next Loops
Explains how to optimize performance of loops.

Related Sections

Decision Structures
Explains control-flow statements used for branching.
With...End With Statements
Describes how to execute several statements on the same object.

Explains control-flow statements inside other control-flow statements.
Exit Statement
Shows how to transfer control directly out of a control-flow statement.

While Statement

You can use the **While** statement to execute a block of statements an indefinite number of times depending on the **Boolean** value of a condition. The statements are repeated as long as the condition is **True**. The condition usually results from a comparison of two values, but it can be any expression that evaluates to a **Boolean** value (**True** or **False**). This includes values of other data types, such as numeric types, that have been converted to **Boolean**.

The **While** statement always checks the condition before it begins the loop. Looping continues while the condition remains **True**.

In the following example, the `CheckWhile` procedure tests the condition before it enters the loop. If `Number` had been initialized to 6 instead of 10, the statements inside the loop would never run.

```
Sub CheckWhile()
   Dim Counter As Integer = 0
   Dim Number As Integer = 10
   While Number > 6
      Number = Number - 1
      Counter = Counter + 1
   End While
   MsgBox("The loop ran " & Counter & " times.")   ' Runs 4 times.
End Sub
```

You can transfer out of a **While** statement by using the **Exit While** statement. One use of this is to test for a condition that could cause an *endless loop*, which is a loop that could run an extremely large or even infinite number of times. If the condition is **True**, use **Exit While** to escape. If the condition is **False**, the loop continues running.

In the following example, `Number` is assigned a value that could cause the loop to execute more than 2 ^ 31 times. The **If** statement checks for this and exits if it exists, preventing endless looping.

```
Sub ExitWhileExample()
   Dim Counter As Integer = 0
   Dim Number As Integer = 8
   While Number <> 10
      If Number < 0 Then Exit While
      Number = Number - 1
      Counter = Counter + 1
   End While
   MsgBox("The loop ran " & Counter & " times.")   ' Runs 9 times.
End Sub
```

Note To stop an endless loop, press ESC or CTRL+BREAK.

Decision Structures | Nested Control Statements | While...End While Statements | Do...Loop Statements | For...Next Statements | For Each...Next Statements | Exit Statement | Boolean Data Type

Do...Loop Statements

You can use **Do...Loop** statements to execute a block of statements an indefinite number of times depending on the **Boolean** value of a condition. The statements can be repeated either while the condition is **True** or until it becomes **True**. The condition usually results from a comparison of two values, but it can be any expression that evaluates to a **Boolean** value (**True** or **False**). This includes values of other data types, such as numeric types, that have been converted to **Boolean**.

Repeating Statements While a Condition Is True

There are two ways to use the **While** keyword to check a condition in a **Do** loop. You can check the condition before you enter the loop, or you can check it after the loop has run at least once. Looping continues while the condition remains **True**.

In the following example, the `CheckWhileFirst` procedure tests the condition before it enters the loop. If `Number` had been initialized to 6 instead of 10, the statements inside the loop would never run. In the `CheckWhileLast` procedure, the statements inside the loop run once before testing the condition, which is **False** on the first test.

```
Sub CheckWhileFirst()
   Dim Counter As Integer = 0
   Dim Number As Integer = 10
   Do While Number > 6
      Number = Number - 1
      Counter = Counter + 1
   Loop
   MsgBox("The loop ran " & Counter & " times.")   ' Runs 4 times.
End Sub
   ' ...
Sub CheckWhileLast()
   Dim Counter As Integer = 0
   Dim Number As Integer = 5
   Do
      Number = Number - 1
      Counter = Counter + 1
   Loop While Number > 6
   MsgBox("The loop ran " & Counter & " times.")   ' Runs 1 time.
End Sub
```

Repeating Statements Until a Condition Becomes True

There are two ways to use the **Until** keyword to check a condition in a **Do** loop. You can check the condition before you enter the loop, or you can check it after the loop has run at least once. Looping continues while the condition remains **False**.

In the following example, the `CheckUntilFirst` procedure tests the condition before it enters the loop. If `Number` had been initialized to 15 instead of 20, the statements inside the loop would never run. In the `CheckUntilLast` procedure, the statements inside the loop run once before testing the condition, which is **False** on the first test.

```
Sub CheckUntilFirst()
   Dim Counter As Integer = 0
   Dim Number As Integer = 20
   Do Until Number = 15
      Number = Number - 1
      Counter = Counter + 1
   Loop
   MsgBox("The loop ran " & Counter & " times.")   ' Runs 5 times.
End Sub
   ' ...
Sub CheckUntilLast()
   Dim Counter As Integer = 0
   Dim Number As Integer = 20
   Do
      Number = Number - 1
      Counter = Counter + 1
   Loop Until Number = 15
   MsgBox("The loop ran " & Counter & " times.")   ' Runs 5 times.
End Sub
```

Exiting a Do Loop from Inside the Loop

You can transfer out of a **Do** loop by using the **Exit Do** statement. One use of this is to test for a condition that could cause an *endless loop*, which is a loop that could run an extremely large or even infinite number of times. If the condition is **True**, use **Exit Do** to escape. If the condition is **False**, the loop continues running.

In the following example, `Number` is assigned a value that could cause the loop to execute more than 2 ^ 31 times. The **If** statement checks for this and exits if it exists, preventing endless looping.

```
Sub ExitDoExample()
   Dim Counter As Integer = 0
   Dim Number As Integer = 8
   Do Until Number = 10
      If Number <= 0 Then Exit Do
      Number = Number - 1
      Counter = Counter + 1
   Loop
   MsgBox("The loop ran " & Counter & " times.")   ' Runs 8 times.
End Sub
```

Note To stop an endless loop, press ESC or CTRL+BREAK.

Replacing the Continue Statement

Visual Basic .NET does not support the **Continue** statement of previous versions of Visual Basic. However, you can achieve the same functionality by putting a statement label on the **Loop** statement and branching to it from the middle of the loop:

```
Dim LoopCounter As Integer = 0
   Do While LoopCounter < 100
      LoopCounter += 1
      Dim SkipToNextIteration As Boolean   ' Local to this loop.
      ' Processing, which might change value of SkipToNextIteration.
      If SkipToNextIteration = True Then GoTo EndOfLoop
      ' More processing if SkipToNextIteration was still False.
EndOfLoop: Loop ' Acts like Continue.
```

For...Next Statements

Do loops work well when you do not know in advance how many times you need to execute the statements in the loop. However, when you expect to execute the loop a specific number of times, a **For...Next** loop is a better choice. Unlike a **Do** loop, a **For** loop uses a variable called a *counter* that increases or decreases in value during each repetition of the loop. The syntax is as follows:

```
For counter [ As datatype ] = start To end [ Step step ]
   ' Statement block to be executed for each value of counter.
Next [ counter ]
```

The variable *counter* must be of a numeric data type that supports the greater than or equal (**>=**), less than or equal (**<=**), and addition (**+**) operators; usually it is **Integer**. The iteration values *start, end,* and *step* are expressions that must evaluate to data types that widen to the type of *counter*. Usually they are also **Integer**. The optional *step* can be positive or negative. If it is omitted, it is taken to be 1.

If *counter* is not declared outside the loop, you can use the **As** clause to declare it as part of the **For** statement.

When execution of the **For...Next** loop begins, Visual Basic evaluates *start, end,* and *step*. It then assigns *start* to *counter*. Before it executes the statement block, it compares *counter* to *end*. If *counter* is already past the end value, the **For** loop terminates and control passes to the statement following the **Next** statement. Otherwise the statement block is executed.

Each time Visual Basic encounters the **Next** statement, it increments the counter by *step* and returns to the **For** statement. Again it compares the counter to *end*, and again it either executes the block or terminates the loop depending on the result. This process continues until the counter passes *end* or an **Exit For** statement is executed.

The loop does not terminate until *counter* has passed the end value. If *counter* is equal to *end*, the loop continues. The comparison that determines whether to execute the block is *counter* **<=** *end* if *step* is positive and *counter* **>=** *end* if *step* is negative.

You can optionally specify *counter* in the **Next** statement. This improves the readability of your program. You must specify the same variable as the one that appears in the **For** statement.

The following procedure presets all the elements of an array to 128. The **For** statement specifies the counter variable `I` and its *start* and *end* values. The **Next** statement increments the counter by 1, because *step* is not supplied.

```
Sub Preset(ByRef A() As Integer)
   Dim I As Integer
   For I = 0 To UBound(A)
      A(I) = 128
   Next I
End Sub
```

The iteration values *start*, *end*, and *step* are evaluated only once, before the loop begins. If your statement block changes *end* or *step*, these changes do not affect the iteration of the loop. In the preceding example, the **UBound** function is called only when the **For** statement is first executed. If the statement block had subsequently changed the length of the array `A`, the **For** loop would still use the original length as the end value, because it does not call **UBound** again.

Incrementing and Decrementing the Counter Variable

Using the **Step** keyword, you can increment or decrement the counter by the value you specify. In the following example, the counter variable `J` is incremented by 2 each time the loop repeats. When the loop is finished, `Total` is the sum of 2, 4, 6, 8, and 10.

```
Sub TwosTotal()
   Dim J, Total As Integer
   For J = 2 To 10 Step 2
      Total = Total + J
   Next J
   MsgBox("The total is " & Total)
End Sub
```

To decrease the counter variable, use a negative **Step** value. When you do this, you should specify an end value that is less than the start value. In the following example, the counter variable `N` is decreased by 2 each time the loop repeats. When the loop is finished, `Total` is the sum of 16, 14, 12, 10, 8, 6, and 4.

```
Sub NewTotal()
   Dim N, Total As Integer
   For N = 16 To 4 Step -2
      Total = Total + N
   Next N
   MsgBox("The total is " & Total)
End Sub
```

Exiting a For...Next Loop Before the Counter Passes Its End Value

You can exit a **For...Next** loop before the counter passes its end value by using the **Exit For** statement. For example, you might want to exit a loop if you detect a condition that makes it unnecessary or impossible to continue iterating, such as an erroneous value or a termination request. Also, if you catch an exception in a **Try...Catch...Finally**, you can use **Exit For** at the end of the **Finally** block.

Decision Structures | Nested Control Statements | For...Next Statements (Language Reference) | Do...Loop Statements | While Statement | For Each...Next Statements | Exit Statement | Data Types | Integer Data Type | UBound Function | Step

For Each...Next Statements

The **For Each...Next** loop is similar to the **For...Next** loop, but it executes the statement block for each element in a collection, instead of a specified number of times. The syntax is as follows:

```
For Each elementvariable [ As datatype ] In collection
   ' Statement block to be executed for each value of elementvariable.
Next [ elementvariable ]
```

The elements of *collection* can be of any data type. The data type of *elementvariable* must be such that each element of the collection can be converted to it.

If *elementvariable* is not declared outside the loop, you can use the **As** clause to declare it as part of the **For Each** statement.

For each iteration of the loop, Visual Basic sets the variable *elementvariable* to one of the elements in the collection and executes the statement block. When all the elements in the collection have been assigned to *elementvariable*, the **For Each** loop terminates and control passes to the statement following the **Next** statement.

You can optionally specify the element variable in the **Next** statement. This improves the readability of your program. You must specify the same variable as the one that appears in the **For Each** statement.

The following procedure accepts a form and sets the background color of every control in that form to light blue:

```
Sub LightBlueBackground(ByVal ThisForm As System.Windows.Forms.Form)
   Dim ThisControl As System.Windows.Forms.Control
   For Each ThisControl In ThisForm.Controls
      ThisControl.BackColor = System.Drawing.Color.LightBlue
   Next ThisControl
End Sub
```

The collection must be an object that implements the **IEnumerable** interface of the **System.Collections** namespace. **IEnumerable** defines the **GetEnumerator** method, which returns an enumerator object for the collection. The enumerator object exposes the **Current** property and the **MoveNext** method. Visual Basic uses these to traverse the collection. The data type of the elements returned by **Current** must be convertible to the data type of *elementvariable*.

Modifying Elements

The **Current** property of the enumerator object is **ReadOnly**, and it returns a local copy of each collection element. This means that you cannot modify the elements themselves in a **For Each...Next** loop. Any modification you make affects only the local copy from **Current** and is not reflected back into the collection. However, if an element is a reference type, you can modify the members of the instance to which it points. This is why, in the previous example, you can modify the `BackColor` member of each `ThisControl` element, although you cannot modify `ThisControl` itself.

Accessing Arrays

Because **System.Array** implements the **IEnumerable** interface, all arrays expose the **GetEnumerator** method. This means you can iterate through an array with a **For Each...Next** loop. However, you can only read the array elements, not change them. The following procedure is intended to find the sum of the elements of an array and reset each element to zero:

```
Function SumAndReset(ByRef A() As Integer) As Integer
   Dim Elt As Integer
   Dim Sum As Integer = 0
   For Each Elt In A
      Sum += Elt
      Elt = 0
   Next Elt
   Return Sum
End Function
```

The summation works as intended because it relies only on reading the elements. However, the resetting to zero does not work as intended, because only the local copy is reset to zero, while the original element is left unchanged in the collection.

Altering the Collection

The enumerator object does not allow you to alter the collection by adding, deleting, replacing, or reordering any elements. If you alter the collection after you have initiated a **For Each...Next** loop, the enumerator object becomes invalid, and the next attempt to access an element results in an **InvalidOperationException**.

Traversing the Collection

When you execute a **For Each...Next** loop, traversal of the collection is under the control of the enumerator object returned by the **GetEnumerator** method. The order of traversal is not determined by Visual Basic, but rather by the **MoveNext** method of the enumerator object. This means that you might not be able to predict which element of the collection is the first to be returned in *elementvariable*, or which is the next to be returned after a given element.

If your code depends on traversing a collection in a particular order, a **For Each...Next** loop is not the best choice unless you know the characteristics of the enumerator object the collection exposes. You might achieve more reliable results using a different loop, such as **For...Next** or **Do...Loop**.

Exiting a For Each...Next Loop Before It Is Finished with the Collection

You can exit a **For Each...Next** loop before it has traversed the collection by using the **Exit For** statement. For example, you might want to exit a loop if you detect a condition that makes it unnecessary or impossible to continue iterating, such as an erroneous value or a termination request. Also, if you catch an exception in a **Try...Catch...Finally**, you can use **Exit For** at the end of the **Finally** block.

Faster For...Next Loops

Integer variables are slightly faster to update than either **Short** or **Long** ones. This difference is noticeable only if you perform many thousands of operations. However, the difference between **Integer** and **Single** or **Decimal** is more readily noticeable. The following example shows some possible variations:

```
Dim Fastest As Integer   ' First case -- Integer is fastest.
For Fastest = 0 to 100000
   ' Statements to execute for each value of Fastest.
Next Fastest
   ' ...
Dim NotAsFast As Long   ' Second case -- Long is not as fast.
For NotAsFast = 0 to 100000
   ' Statements to execute for each value of NotAsFast.
Next NotAsFast
   ' ...
Dim MuchSlower As Decimal   ' Third case -- Decimal is slower.
For MuchSlower = 0 to 100000
   ' Statements to execute for each value of MuchSlower.
Next MuchSlower
```

The first case above takes slightly less time to run than the second case. However, an error occurs if `Fastest` exceeds 2,147,483,647. The second or third cases fix this, because both **Long** and **Decimal** types accept a wider range of integers, but they run more slowly. For data types that use 4 or more bytes, smaller types usually take less time to manipulate than larger ones.

With...End With Statements

In Visual Basic you usually must specify an object in every statement that calls one of its methods or accesses one of its properties. However, if you have a series of statements that all operate on the same object, you can use a **With...End With** statement to specify the object once for all of the statements. Doing this can make your procedures run faster and help you avoid repetitive typing.

The following example sets the foreground color and font style of a label depending on the value of a procedure argument.

```
Dim AlertLabel As New System.Windows.Forms.Label
   ' ...
Sub AlertUser(ByVal Value As Long)
   With AlertLabel
      If Value = 0 Then
         .ForeColor = Color.Red
         .Font = New Font(.Font, FontStyle.Bold Or FontStyle.Italic)
      Else
         .Forecolor = Color.Black
         .Font = New Font(.Font, FontStyle.Regular)
      End If
   End With
End Sub
```

You can nest **With...End With** statements for greater efficiency. The following example inserts a formula into cell A1, and then formats the font.

```
Sub MyInput()
   With Workbooks("Book1").Worksheets("Sheet1").Cells(1, 1)
      .Formula = "=SQRT(50)"
      With .Font
         .Name = "Arial"
         .Bold = True
          .Size = 8
      End With
   End With
End Sub
```

Decision Structures | Loop Structures | With...End With Statements (Language Reference) | Nested Control Statements

Nested Control Statements

You can place control statements inside other control statements, for example an **If...Then...Else** block within a **For...Next** loop. A control statement placed inside another control statement is said to be *nested*.

Control statements in Visual Basic can be nested to as many levels as you want. It is common practice to make nested decision structures and loops more readable by indenting the body of each one.

In the following example, the procedure adds together the positive elements of each row of the matrix:

```
Public Sub SumRows(ByVal A(,) As Double, ByRef R() As Double)
   Dim I, J As Integer
   For I = 0 To UBound(A, 1)
   R(I) = 0
      For J = 0 To UBound(A, 2)
       If A(I, J) > 0 Then
         R(I) = R(I) + A(I, J)
       End If
      Next J
   Next I
End Sub
```

Notice that the first **Next** closes the inner **For** loop and the last **Next** closes the outer **For** loop. Likewise, in nested **If** statements, the **End If** statements automatically apply to the nearest prior **If** statement. Nested **Do** loops work in a similar fashion, with the innermost **Loop** statement matching the innermost **Do** statement.

See Also

Decision Structures | Loop Structures | With...End With Statements | Exit Statement

Exit Statement

The **Exit** statement allows you to exit directly from any decision structure, loop, or procedure. It immediately transfers execution to the statement following the last control statement. The syntax for the **Exit** statement specifies which type of control statement you are transferring out of. The following versions of the **Exit** statement are possible:

- **Exit Select**
- **Exit Try**
- **Exit Do**
- **Exit While**
- **Exit For**

You can also exit directly from a **Function**, **Sub**, or **Property** procedure; the syntax is similar to that of **Exit For** and **Exit Do**:

- **Exit Sub**
- **Exit Function**
- **Exit Property**

Exit Sub, **Exit Function**, and **Exit Property** can appear as many times as needed, anywhere within the body of the procedure. They can even appear inside a control statement such as **If...Then...Else**. These statements are useful when a procedure has done everything it needs to do and can return immediately.

Exiting from Nested Control Statements

If an **Exit** statement is encountered within nested control statements, execution continues with the statement following the end of the innermost control statement of the kind specified in the **Exit** statement. In the following example, the **Exit For** statement is located in the inner **For** loop, so it passes control to the statement following that loop and continues with the outer **For** loop.

```
Public Sub InvertElements(ByRef A(,) As Double)
   Dim I, J As Integer
   For I = 0 To UBound(A, 1)
      For J = 0 To UBound(A, 2)
       If A(I, J) = 0 Then
         Exit For     ' Cannot complete this row.
       Else
         A(I, J) = 1 / A(I, J)
       End If
      ' Control comes here if the Exit For is executed.
      Next J
   Next I
End Sub
```

Multiple Exit Statements

The **Exit** statement in any of its forms can appear as many times as needed inside the appropriate loop or statement. The following example shows this inside a **Do** loop:

```
Dim x, y, z As Double
Do Until y = -1
   If x < 0 Then Exit Do
   x = Math.Sqrt(x)
   If y > 0 Then Exit Do
   y = y + 3
   If z = 0 Then Exit Do
   z = x / z
Loop
```

The **Exit Do** statement works with all versions of **Do** loop syntax (with **While** or **Until**), and **Exit For** works with all versions of **For** loop syntax (with or without **Each**).

Object-Oriented Programming in Visual Basic

Objects are central to Visual Basic programming. Forms and controls are objects. Databases are objects. If you've used Visual Basic for a while, or if you've worked through the examples in this Help file, then you've already programmed with objects, but there's a lot more to objects than what you've seen so far.

In the following topics, you'll see how easy it is to create your own objects from the classes you define, and to use objects to simplify your coding and increase code reuse.

In This Section

Introduction to Objects in Visual Basic
Provides an introduction to the terms and concepts used in object-oriented programming.
Early and Late Binding
Describes binding, which is performed by the compiler when an object is assigned to an object variable, and the differences between early-bound and late-bound objects.
Shared Members
Describes members that can be used without instances.
Creating and Using Objects
Shows how to create and use instances of classes.
Managing Groups of Objects
Provides techniques for working with arrays and collections of objects.
Obtaining Class Information at Run Time
Shows how to determine the class that an object belongs to.
Understanding Classes
Covers object creation and lifetime issues in a step-by-step procedure.
Events and Delegates
Shows how to declare and use events and delegates.
Interfaces in Visual Basic .NET
Describes what interfaces are and how you can use them in your applications.
Inheritance
Describes how to define classes that serve as the basis for other classes.

Objects

Describes what objects are and how they are used.

Programming with Components

Demonstrates how you can use Visual Basic to control objects provided by other applications.

Introduction to Objects in Visual Basic

Almost everything you do in Visual Basic is associated with objects. If you are new to object-oriented programming, the following terms and concepts will help you get started.

Classes and Objects

The words "class" and "object" are used so much in object-oriented programming that it is easy to get the terms mixed up. Generally speaking, a *class* is an abstract representation of something, whereas an *object* is a usable example of the thing the class represents. The one exception to this rule is shared class members, which are usable in both instances of a class and object variables declared as the type of the class.

Fields, Properties, Methods, and Events

Classes are made of fields, properties, methods, and events. Fields and properties represent information that an object contains. Fields are like variables in that they can be read or set directly. For example, if you have an object named Car you could store its color in a field named Color.

Properties are retrieved and set like fields, but are implemented using **Property Get** and **Property Set** procedures, which provide more control on how values are set or returned. The layer of indirection between the value being stored and the procedures that use this value helps isolate your data and allows you to validate values before they are assigned or retrieved.

Methods represent actions that an object can perform. For example, a Car object could have StartEngine, Drive, and Stop methods. You define methods by adding procedures, either **Sub** routines or functions, to your class.

Events are notifications an object receives from, or transmits to, other objects or applications. Events allow objects to perform actions whenever a specific occurrence takes place. An example of an event for the Car class would be a Check_Engine event. Because Microsoft Windows is an event-driven operating system, events can come from other objects, applications, or user input such as mouse clicks or key presses.

Encapsulation, Inheritance, and Polymorphism

Fields, properties, methods, and events are only one half of the object-oriented programming equation. True object-orient programming requires objects to support three qualities: encapsulation, inheritance, and polymorphism.

Encapsulation means that a group of related properties, methods, and other members are treated as a single unit or object. Objects can control how properties are changed and methods are executed. For example, an object can validate values before allowing property changes. Encapsulation also makes it easier to change your implementation at a latter date by letting you hide implementation details of your objects, a practice called *data hiding*.

Inheritance describes the ability to create new classes based on an existing class. The new class inherits all the properties and methods and events of the base class, and can be customized with additional properties and methods. For example, you can create a new class named Truck based on the Car class. The Truck class inherits the Color property from the Car class and can have additional properties such as FourWheelDrive.

Polymorphism means that you can have multiple classes that can be used interchangeably, even though each class implements the same properties or methods in different ways. Polymorphism is essential to object-oriented programming because it allows you to use items with the same names, no matter what type of object is in use at the moment. For example, given a base class of Car, polymorphism enables the programmer to define different StartEngine methods for any number of derived classes. The StartEngine method of a derived class named DieselCar may be completely different from the method with the same name in the base class. Other procedures or methods can use the StartEngine method of the derived classes in exactly the same way, no matter what type of Car object is being used at the time.

Overloading, Overriding, and Shadowing

Overloading, overriding, and shadowing are similar concepts that can be easy to confuse. Although all three techniques allow you to create members with the same name, there are some important differences.

- Overloaded members are used to provide different versions of a property or method that have the same name, but that accept different number of parameters, or parameters with different data types.
- Overridden properties and methods are used to replace an inherited property or method that is not appropriate in a derived class. Overridden members must accept the same data type and number of arguments. Derived classes inherit overridden members.
- Shadowed members are used to locally replace a member that has broader scope. Any type can shadow any other type. For

example, you can declare a property that shadows an inherited method with the same name. Shadowed members cannot be inherited.

Early and Late Binding

The Visual Basic compiler performs a process called *binding* when an object is assigned to an object variable. An object is *early bound* when it is assigned to a variable declared to be of a specific object type. Early bound objects allow the compiler to allocate memory and perform other optimizations before an application executes. For example, the following code fragment declares a variable to be of type **FileStream**:

```
' Add Imports statements to the top of your file.
Imports System.IO
'...
'  Create a variable to hold a new object.
   Dim FS As FileStream
  ' Assign a new object to the variable.
   FS = New FileStream("C:\tmp.txt", FileMode.Open)
```

Because **FileStream** is a specific object type, the instance assigned to `FS` is early bound.

By contrast, an object is *late bound* when it is assigned to a variable declared to be of type **Object**. Objects of this type can hold references to any object, but lack many of the advantages of early-bound objects. For example, the following code fragment declares an object variable to hold an object returned by the **CreateObject** function:

```
' To use this example, you must have Microsoft Excel installed on your computer.
Option Strict Off ' Option Strict Off allows late binding.
...
Sub TestLateBinding()
   Dim xlApp As Object
   Dim xlBook As Object
   Dim xlSheet As Object
   xlApp = CreateObject("Excel.Application")
   'Late bind an instance of an Excel workbook.
   xlBook = xlApp.Workbooks.Add
   'Late bind an instance of an Excel worksheet.
   xlSheet = xlBook.Worksheets(1)
   xlSheet.Activate()
   xlSheet.Application.Visible = True ' Show the application.
   ' Place some text in the second row of the sheet.
   xlSheet.Cells(2, 2) = "This is column B row 2"
End Sub
```

You should use early-bound objects whenever possible, because they allow the compiler to make important optimizations that yield more efficient applications. Early-bound objects are significantly faster than late-bound objects and make your code easier to read and maintain by stating exactly what kind of objects are being used. Another advantage to early binding is that it enables useful features such as automatic code completion and Dynamic Help because the Visual Studio .NET integrated development environment (IDE) can determine exactly what type of object you are working with as you edit the code. Early binding reduces the number and severity of run-time errors because it allows the compiler to report errors when a program is compiled.

> **Note** Late binding can only be used to access type members that are declared as **Public**. Accessing members declared as **Friend** or **Protected Friend** results in a runtime error.

Object Lifetime: How Objects Are Created and Destroyed | Object Data Type | CreateObject Function

Shared Members

Shared members are properties, procedures, and fields that are shared by all instances of a class. Some programming languages refer to such items as *static members*.

Shared fields and properties are useful when you have information that is part of a class, but is not specific to any one instance of a class. Normal fields and properties exist independently for each instance of a class. Changing the value of a field or property associated with any one instance does not affect the value of fields or properties of other instances of the class. On the other hand, when you change the value of a shared field and property associated with an instance of a class, you change the value associated with all instances of the class. In this way, shared fields and properties behave like global variables that can be accessed only from instances of a class. Without static fields and properties, you would need to use module-level variables to achieve the same effect. However, module-level variables can make your classes difficult to understand and maintain. Furthermore, using module-level variables in this way violates the concept of encapsulation that classes represent.

Shared procedures are class methods that are not associated with a specific instance of a class. For example, the **Cos** method defined within the **Math** class is a shared method. You can call a shared procedure by calling it either as a method of an object, or directly from the class. In this way, shared procedures represent an exception to the rule that you must create an instance of a class before you can use it.

Shared procedures are not implicitly passed instances of the class. For this reason, no unqualified references to non-shared data members are allowed in shared methods.

Shared Members Example

The following example creates an instance field, a shared field, and a shared method to demonstrate how shared members operate in code:

```
Public Class ShareClass
   Public InstanceValue As String
   Public Shared SharedValue As String
   Public Shared Sub ShareMethod()
      MsgBox("This is a shared method.")
   End Sub
End Class
Sub TestShared()
   Dim Shared1 As New ShareClass()   ' Create an instance of the class.
   Dim Shared2 As New ShareClass()   ' Create an instance of the class.
   Shared1.SharedValue = "Share Value 1"    ' Set the value of a shared field.
   Shared2.SharedValue = "Share Value 2"   ' Overwrite the first value.
   MsgBox("The value of the shared field in the first instance" & _
      "is: " & Shared1.SharedValue)
   MsgBox("The value of the shared field in the second instance" & _
      "is: " & Shared2.SharedValue)
   ' Call a method on the class without creating an instance.
   ShareClass.ShareMethod()
End Sub
```

When you execute the `TestShared` procedure, two instances of the class are created, and the shared field `SharedValue` is modified for both instances. When the shared field in the second instance of the class is modified, the value assigned to the shared field in the first instance of the class is overwritten because both instances refer to the same field.

For the sake of clarity, this example uses object variables to access shared members, but it is better programming practice to access shared members directly using the class name; for example, `ShareClass.SharedValue = "Share Value 2"`. Using class syntax for shared members reduces confusion, because it makes it clear when you are using shared members and when you are using instance members.

Creating and Using Objects

Objects are combinations of code and data that can be treated as single units. Nearly everything you do in Visual Basic .NET involves objects, from the controls you use to the forms on which you place them. This section discusses where objects originate and how to use them.

In This Section

Objects from Visual Basic and Other Sources
Discusses how to use objects from Microsoft Word, Microsoft Excel, and other applications.
Setting and Retrieving Properties
Discusses how to change and obtain property values.
Performing Actions with Methods
Describes what methods are and how to use them.
Performing Multiple Actions on an Object
Covers using the **With...End With** statement to simplify property access.
Treating Forms as Objects
Shows how to use forms in the same way as ordinary objects.
Using the New Keyword
Shows how to create instances of forms, classes defined in class modules, and collections.

Objects from Visual Basic and Other Sources

The objects you use in Visual Basic .NET come from both internal and external sources. Examples of internal objects include intrinsic objects and classes in your project; examples of external objects include assemblies and COM objects.

Internal Objects

Intrinsic (or *built-in*) objects are objects that Visual Basic .NET natively provides. These include the primitive scalar types such as **Integer** and **Double** as well as the **Array** and **String** types. You do not need to create references to internal objects before using them in your project.

Other internal objects are instances of classes in your current project. You can use these classes wherever necessary within your project, and you can make them available for use by other applications when you create an assembly.

External Objects

External objects are those that come from other projects or assemblies that are not available to your project by default. You must create project references to external objects before using them in your project.

Assemblies are the most common source of objects for Visual Basic .NET applications. The .NET Framework includes assemblies that contain commonly used objects. Some objects in the .NET Framework are treated as intrinsic objects, but most assemblies must be explicitly imported using the **Imports** statement before they can be used. Any language compliant with the Common Language Specification (CLS), such as Visual Basic .NET or Visual C#, can create and use assemblies. For details, see Assemblies.

In the past, COM components were a traditional source of objects for Visual Basic programmers, but today .NET assemblies are a better choice for new objects. You can still use existing COM components in your applications; however, COM objects must be accessed via .NET interoperability classes. Accessing a COM library requires the use of an interoperability assembly containing interoperability classes for each COM class defined within the COM library.

In addition to accessing native .NET classes and COM classes, it is also possible to call functions defined in dynamic-link libraries (DLL's). Visual Basic .NET allows you to call functions in DLL's after they have been declared with a **Declare** statement. Visual Basic .NET adds functionality to the **Declare** statement by allowing you use the **DllImport** attribute to specify defaults for things such as **CallingConvention**, **ExactSpelling,** and **SetLastError**. Parameters for **Declare** statements can be annotated with the **MarshalAs** attribute, which supports conversion of parameters in ways that were not possible in earlier versions of Visual Basic.

Setting and Retrieving Properties

When working with forms and controls in Visual Basic .NET, you can set their properties programmatically at run time, or you can set them in design mode using the **Properties** window. The properties of most other objects, such as objects from assemblies or objects you create, can only be set programmatically.

Properties you can set and read are called *read-write* properties. Properties you can read but not modify are called *read-only* properties. Properties you can write but not read are called *write-only* properties.

You set the value of a property when you want to change the appearance or behavior of an object. For example, you change the **Text** property of a text box control to modify the contents of the text box.

You get the value of a property when you want to find the state of an object before your code performs additional actions, such as assigning the value to another object. For example, you can return the **Text** property of a text box control to determine the contents of the text box before running code that might change the value.

To set property values

- Use the following syntax:

```
object.property = expression
```

The following statements provide examples of how to set properties:

```
TextBox1.Top = 200   ' Sets the Top property to 200 twips.
TextBox1.Visible = True   ' Displays the text box.
TextBox1.Text = "hello"   ' Displays 'hello' in the text box.
```

Note You can also set a property by passing it to **ByRef** parameters, in which case the property is modified by the result returned by the **ByRef** parameter.

To get property values

- Use the following syntax:

```
variable = object.property
```

You can also get a property value as part of a more complex expression, without assigning the property to a variable. The following code changes the **Top** property of a radio button control:

```
Protected Sub RadioButton1_CheckedChanged(ByVal sender As Object, _
      ByVal e As System.EventArgs)
   ' [statements]
   RadioButton1.Top += 20
   ' [statements]
End Sub
```

The Basics of Working with Objects | Performing Actions with Methods | Objects from Visual Basic and Other Sources | Creating and Using Objects

Performing Actions with Methods

Methods are procedures associated with objects. Unlike fields and properties, which represent information an object can store, methods represent actions that an object can perform. Methods can affect the values of properties. For example, to use a radio analogy, you can employ a `SetVolume` method to change the value of a `Volume` property. Similarly, in Visual Basic .NET, the items of list boxes have a **List** property, which you can change with the **Clear** and **Add** methods.

When you use a method in code, the way you write the statement depends on how many arguments the method requires and whether it returns a value. Generally, you use methods just like you use subroutines or function calls. More specifically, you invoke methods in the same way as module procedures, except that you can qualify methods with an expression specifying the object instance whose method is to be called. When unqualified, the instance is implicitly the **Me** variable.

To use a method that does not require arguments

- Use the following syntax:

```
object.method()
```

In the following example, the **Refresh** method repaints the picture box:

```
PictureBox1.Refresh()   ' Forces a repaint of the control
```

Note Some methods, such as **Refresh**, do not have arguments and do not return values.

To use a method that requires multiple arguments

- Place the arguments in parentheses and separate them with commas. In the following example, the **MsgBox** method uses arguments that specify the message to display and the style of the message box:

```
MsgBox("Database update complete", _
       MsgBoxStyle.OKOnly Or MsgBoxStyle.Exclamation, _
       "My Application")
```

To use a method that returns a value

- Assign the return value to a variable, or directly use the method call as a parameter to another call. The following code stores the return value:

```
Dim Response As MsgBoxResult
Response = MsgBox("Do you want to exit?", _
                  MessageBoxButtons.YesNo Or MsgBoxStyle.Question, _
                  "My Application")
```

This example uses the value returned from the Len method as an argument to MsgBox.

```
Dim MyStr As String = "Some String"
'   Displays "String length is : 11
MsgBox("String length is : " & Len(MyStr))
```

See Also

The Basics of Working with Objects | Relation of Objects to Each Other | Setting and Retrieving Properties | Creating and Using Objects

Performing Multiple Actions on an Object

Often, you need to perform several different actions on the same object. For example, you may need to set several properties or execute several methods for the same object.

To set multiple properties for the same object

- One way to do this is to write several statements using the same object variable, as in the following code:

```
Private Sub UpdateForm()

   Button1.Text = "OK"

   Button1.Visible = True

   Button1.Top = 24

   Button1.Left = 100

   Button1.Enabled = True

   Button1.Refresh()

End Sub
```

However, you can make this code easier to write and read by using the **With...End With** statement, as in the following code:

```
Private Sub UpdateForm2()

   With Button1

      .Text = "OK"

      .Visible = True

      .Top = 24

      .Left = 100

      .Enabled = True

      .Refresh()

   End With

End Sub
```

You can also nest **With...End With** statements by placing one inside another, as in the following code:

```
Sub SetupForm()
   Dim AnotherForm As New Form1()
   With AnotherForm
      .Show()   ' Show the new form.
      .Top = 250
      .Left = 250
      .ForeColor = Color.LightBlue
      .BackColor = Color.DarkBlue
      With AnotherForm.Textbox1
         .BackColor = Color.Thistle   ' Change the background.
         .Text = "Some Text"   ' Place some text in the text box.
      End With
   End With
End Sub
```

Within the nested **With** statement, however, the syntax refers to the nested object; properties of the object in the outer **With** statement are not set.

Calling a Property or Method Using a String Name

Treating Forms as Objects

Forms are graphical objects that make up your applications user interface. Within Visual Basic, classes define how forms are displayed and what they can do. When a form is displayed at runtime, Visual Basic .NET creates an instance of the **Form** class that you can use like any other object. You can add custom methods and properties to forms and access them from other forms or classes in your application.

To create a new method for a form

- Add a procedure declared as **Public**, as in the following code:

```
' Create a custom method on a form.
Public Sub PrintMyJob()
   '.
   '.Add code for your method here.
   '.
End Sub
```

To add a new field to a form

- Declare a public variable in the form module, as in the following code:

```
Public IDNumber As Integer
```

To access methods on a different form

1. Create a new instance of the form whose methods you want to access. When you reference a form name, you are actually referencing the class the form belongs to, not the object itself.

   Note Visual Basic 6 provided, for each form class, an implicit global variable with the same name as the form class. Visual Basic .NET does not provide an implicit variable declaration.

2. Assign the form to an object variable. The object variable references a new instance of the form class.

   The following example correctly calls the `PrintMyJob` procedure:

```
Dim newForm1 As New Form1
newForm1.PrintMyJob
```

In the previous example, the new form is not displayed. It is not necessary to show a form object to use its methods. To display the new form, you need to add the following code:

```
newForm1.show
```

Property Procedures | Using the New Keyword

Using the New Keyword

To create an instance of a class, use the **New** keyword. Unlike value types, such as **Integer** and **Double**, objects are reference types, and you must explicitly create them before you can use them. For example, consider the following two lines of code:

```
Dim Button1 As System.Windows.Forms.Button
```

```
Dim Button2 As New System.Windows.Forms.Button()
```

The first statement declares an object variable that can contain a reference to a button object. However, the variable `Button1` contains the value **Nothing** until you assign an object of type **Button** to it. The second statement also defines a variable that can contain a button object, but the **New** keyword creates a button object and assigns it to the variable `Button2`.

Because forms and controls are actually classes, you can use the **New** keyword to create new instances of these items as needed.

To create new instances of a class with New

1. Open a new Windows Forms project and place a command button and several other controls on a form named `Form1`.
2. Add the following code to the command button's **Click** event procedure:

```
Dim f As New Form1
f.Show
```

3. Run the application, and click the command button several times.
4. Move the front form aside. Because a form is a class with a visible interface, you can see the additional copies. Each copy has the same controls, in the same positions as those on the original form at design time.

You can use the **New** keyword to create objects from within classes. The following procedure provides an example.

To see how New creates instances of a class

1. Open a new project, and place a command button on a form named `Form1`.
2. From the **Project** menu, choose **Add Class** to add a class to the project.
3. Name the new class `ShowMe.vb`.
4. Add the following procedure to `ShowMe`:

```
Public Class ShowMe
   Sub ShowFrm()
      Dim frmNew As Form1
      frmNew = New Form1
      frmNew.Show()
      frmNew.WindowState = 1
   End Sub
End Class
```

5. Add the following code to the **Button1_Click** event of the button on your form:

```
Protected Sub Button1_Click(ByVal sender As System.Object, _
      ByVal e As System.EventArgs) Handles Button1.Click
   Dim clsNew As New ShowMe()
   clsNew.ShowFrm()
End Sub
```

6. To use the example, run the application and click the command button several times. A minimized form icon appears on your taskbar as each new instance of the `ShowMe` class is created.

Creating and Using Objects

Resource Management

All objects consume system resources such as memory, file handles, and database connections. The Common Language Runtime (CLR) manages resources automatically, and you usually do not need to worry about releasing unneeded objects. However, understanding resource management works can help you design your applications to be more efficient.

Garbage Collection

The CLR uses a system called garbage collection to manage allocated resources. The system garbage collector releases an object's resources when that object can no longer be reached by any running code in your application. The following sections describe some of the changes to the way resources are managed in Visual Basic .NET.

Assigning Objects to Nothing

Nothing is a keyword used by Visual Basic .NET to indicate that an object variable does not contain a reference to an object. Previous versions of Microsoft Visual Basic encouraged you to assign unused objects to **Nothing** to disassociate the object variable from the object and release resources. You can still assign unused objects to **Nothing**, but because of the way Visual Basic .NET manages resources this process does not guarantee that objects will be released immediately. Generally speaking, you should only assign objects to **Nothing** for long-lived objects such as shared members or global variables.

Dispose

Some objects support a method named **Dispose** whose purpose is to release system resources more expeditiously. Classes that support the Dispose method should implement the **IDisposable** interface. The **Dispose** method needs to be explicitly called when you want to release object resources. For example:

```
ThisObject.Dispose
```

Finalize

Another method supported by some classes, **Finalize**, runs automatically when an object is released and can be used to perform other cleanup tasks. The **Finalize** method is similar to the **Class_Terminate()** method used in previous versions of Microsoft Visual Basic. Unlike the **Dispose** method, the CLR automatically calls the **Finalize** method sometime after an object is no longer needed.

See Also

Nothing | Object Lifetime: How Objects Are Created and Destroyed | Initialization and Termination of Components | IDisposable.Dispose Method | IDisposable Interface

Passing Objects to Procedures

Visual Basic .NET allows you to pass objects as arguments to procedures in the same way that you pass other types of arguments. The following procedures demonstrate how.

To pass a new instance of a form to a procedure

1. Open a project, create a new form and add a command button named `Button1` to it.
2. Copy the following code into the `Button1_click` event:

```
Protected Sub Button1_Click(ByVal sender As System.Object, _
       ByVal e As System.EventArgs)
   Dim newForm As New Form1()
   newForm.Show()
   CenterForm(newForm)
End Sub

Sub CenterForm(ByVal TheForm As Form)
   ' Centers the form on the screen.
   Dim RecForm As rectangle = Screen.GetBounds(TheForm)
   TheForm.Left = CInt((RecForm.Width - TheForm.Width) / 2)
   TheForm.Top = CInt((RecForm.Height - TheForm.Height) / 2)
End Sub
```

You can also pass an object as an argument by reference and then, inside the procedure, set the argument to a new object.

To pass an object reference to a procedure on another form

1. Open a project and create a form named `Form1`.
2. Add a second form named `Form2`.
3. Place a picture box control on each form.
4. Name the picture box on form1 `PictureBox1`.
5. Name the picture box on form2 `PictureBox2`.
6. Assign a picture to `PictureBox2` by clicking the **Image** property in the **Properties** window. Any small images will work; you can find .bmp and .jpg files in your Windows directory.
7. Add the following code to `Form2`:

```
Public Sub GetPicture(ByVal x As PictureBox)
   Dim objX As PictureBox
   ' Assign the passed-in picture box to an object variable.
   objX = x
   ' Assign the value of the Picture property to the Form1 picture box.
   objX.Image = PictureBox2.Image
End Sub
```

8. Add the following code to the **Form1_Click** event on `form1`:

```
Protected Sub Form1_Click(ByVal sender As System.Object, _
      ByVal e As System.EventArgs)
   Dim newForm2 As New Form2()
   newForm2.GetPicture(PictureBox1)
End Sub
```

9. Run the application and click `Form1`. The picture from `Form2` appears in the picture box on `Form1`.

   The **Form1_Click** event procedure calls the `GetPicture` procedure in `Form2`, and passes the empty picture box to it. The `GetPicture` procedure in `Form2` assigns the **Image** property of the picture box on `Form2` to the empty picture box on `Form1`, and the image from `Form2` is displayed on `Form1`.

Managing Groups of Objects

For many applications, you want to be able to create and manage groups of related objects. There are two ways to group objects: by creating arrays of objects, and by creating collections.

Arrays are relatively inflexible structures. If you want to change the size of the array at run time, you must use the **ReDim** statement to redeclare it. All members of the array must be of the same type. On the other hand, arrays allow you to sequentially process all your objects, and you can have empty members of an array. For these reasons, arrays are most useful for creating and working with a fixed number of strongly typed objects.

Collections provide a more flexible way of working with groups of objects. A collection is a class, so you must declare a new collection before you can add members to that collection. Unlike arrays, the group of objects you work with can grow and shrink dynamically as the needs of the program change. You can assign a key to any object that you put into a collection so that you can retrieve and manipulate it based on that key.

In This Section

Creating Arrays of Objects
Demonstrates how to declare an array and instantiate its members.
Collections in Visual Basic .NET
Provides an overview of collections, discussing the **Collection** class, zero-based and one-based collections, index and key values, and how to add and remove items.
Creating Collections of Objects
Describes how to create a collection and use **For...Each...Next** to process its members.
The Visual Basic .NET Collection Class
Discusses the **Collection** class, what kinds of items you can add to a collection, and how to access the members after adding them.
Properties and Methods of the Collection Class
Describes the properties (**Count** and **Item**) and methods (**Add** and **Remove**) with which you can manipulate items in a **Collection** object.
Adding, Deleting, and Retrieving Items from a Collection
Explains how to add, retrieve, and delete items from a collection.

Related Sections

Creating and Using Objects
Shows how to create and use instances of classes.
Arrays
Discusses making your code more compact and powerful by declaring and using arrays.

Creating Arrays of Objects

You declare and use arrays of an object type just as you would declare and use an array of any data type. The members of this array can be retrieved by their index, and can be manipulated as any object of this type would be. Arrays also have built-in functionality for searching and sorting that can be accessed through the array variable. For more information on these methods, see Array Class.

To create an array of objects

1. Declare the array as shown in the sample code below. Because arrays are zero-based, they contain one member more than the upper bound you declare.

```
Dim x(10) As Widget   ' Contains 11 members, from x(0) to x(10).
```

2. Instantiate each member of the array, or assign each member a reference to an already existing object. An example of each approach is shown below:

```
' Instantiates each member of an array by using a loop.
Dim q As Integer
For q = 0 to 10
   x(q) = New Widget()
Next

' Assigns a member of an array a reference to an existing object.
Dim myWidget As New Widget()
x(0) = myWidget
x(1) = myWidget
```

   Note that you can assign the different members of the array references to the same object.

Arrays | Array Class | Creating Collections of Objects

Collections in Visual Basic .NET

In general terms, a collection is a way of grouping and managing related objects. This simple definition, however, describes a somewhat complex reality.

Every form, for example, has a **Controls** collection. This is an object that represents all the controls on that form. It allows you to obtain a reference to a control in the collection by its index, and to loop through the members of the collection using **For Each...Next** statements.

Visual Basic also provides a **Collection** class, with which you can define and create your own collections. Like a form's **Controls** collection, the **Collection** class also provides you with the built-in functionality to loop through members using **For Each...Next** and to reference members by index. Since both are collections, why then does the following code from a Windows Forms application generate a compiler error?

```
Dim myControlsCollection As Collection
myControlsCollection = Controls   ' This line generates a compiler error.
```

What's happening here? The **Controls** collection is a collection; the variable `myControlsCollection` is declared as **Collection**; why can't you assign a reference to **Controls** to the variable `myControlsCollection`?

The reason is that the **Collection** class and the **Controls** collection are not polymorphic; that is, they aren't interchangeable, because they are different types with different implementations. They don't have the same methods, store object references in the same way, or use the same kinds of index values.

These differences make the **Collection** class's name seem like an odd choice, because it really represents only one of many possible collection implementations. This topic explores some of these implementation differences.

Zero-Based and One-Based Collections

A collection is either zero-based or one-based, depending on what its starting index is. As you might guess, the former means that the index of the first item in the collection is zero, and the latter means that it is one. An example of a zero-based collection is the **Controls** collection, discussed above. An instance of the **Collection** object, also discussed above, is an example of a one-based collection.

One-based collections are more intuitive to use, because the index ranges from one to **Count**, where the **Count** property returns the number of items in a collection. The index of a zero-based collection, by contrast, ranges from zero to one less than the **Count** property.

The .NET Framework is standardizing collection as being zero-based. The Visual Basic Collection class is one based primarily for the purpose of compatibility with previous versions.

Index and Key Values

Many collections in Visual Basic allow you to access an item using either a numeric index or a **String** key, as do instances of the Visual Basic **Collection** class. You may also add items to **Collection** objects without specifying a key.

By contrast, some collections (such as **System.Collections.ArrayList**) allow only a numeric index. These collections provide access to their members only through the index, and do not allow you to associate a key.

Adding and Removing Items

Collections also differ in whether or not you can add items to them, and if so, how those items are added. Because the Visual Basic **Collection** object is a general-purpose programming tool, it's more flexible than other collections. It has an **Add** method for putting items into the collection, and a **Remove** method for taking items out.

Certain specialized collections, on the other hand, do not allow developers to add and remove members using code. For example, the **CheckedListBox.CheckedItems** property returns references to items by index, but you cannot add and remove items from the collection in code. Rather you can only do so by checking or unchecking the appropriate box in the visual interface. Thus there is no **Add** or **Remove** method for this collection.

See Also

Walkthrough: Creating Your Own Collection Class | Collections in Visual Basic .NET | Creating Collections of Objects | The Visual Basic .NET Collection Class | For Each...Next Statements | Count Property | Add Method | Remove Method |

Creating Collections of Objects

Collections are objects themselves. The first step in creating a collection of objects is to create the **Collection** object itself. Once the **Collection** object is created, items can be added, removed, and otherwise manipulated through it. In this example, you learn how to create and populate a **Collection** object.

To create a collection

1. Declare and instantiate a **Collection** variable as shown in the sample code below:

```
Dim myCollection As New Collection()
```

2. Use the **Add** method to add members to your collection. In this example, you create four strings and add them to your collection. A unique **String** value may optionally be added as the key for the members of your collection. This value is passed to the collection as the second argument of the **Add** method.

```
Dim w, x, y, z As String
w = "Wow!"
x = "It's"
y = "A"
z = "Collection"
myCollection.Add(w, "This")
myCollection.Add(x, "Is")
myCollection.Add(y, "A")
myCollection.Add(z, "Key")
```

3. If you want to remove any members of your collection, you can use the **Remove** method to do so based either on the index of the member, or on the optional key. Examples are shown below:

```
myCollection.Remove(1)   ' Removes the first member of the collection.
myCollection.Remove("Is")   ' Removes the member with the key "Is".
```

   Note that when a member is removed from a collection, the index values are renumbered from one to the **Count** value.

You can use the **For Each...Next** statement to loop through and process the members of your collection, as in the continuation of our example below.

To use For Each...Next to process the members of your collection

1. Declare a variable of the type you want to process in your collection. For example, if you want to loop through all your strings, declare a variable of type **String**, as shown below:

```
' Code from the previous example goes here.
Dim aString As String
```

2. Use the **For Each...Next** statement to examine each member of your collection. In this example, you search for a particular string, and if you find it, display it in a message box.

```
For Each aString in myCollection
   If aString = "Collection" Then
      MsgBox(aString)   ' Displays "Collection".
   End If
Next
```

Is Operator | The Visual Basic .NET Collection Class | Creating Arrays of Objects | Walkthrough: Creating Your Own Collection Class | Collection Object | Add Method | Remove Method | For Each...Next Statements

The Visual Basic .NET Collection Class

A collection is a way of grouping a set of related items. Many different types of collections exist. Collections are used in Visual Basic to keep track of many things, such as all the controls on a form (the **Controls** collection for example), and users can create their own collections to organize and manipulate objects.

Collections are a good way to keep track of objects that your application might need to dynamically create and destroy. The following code fragment shows how you might use the **Add** method of a collection object to keep a list of `Widget` objects the user has created.

```
' Declares and instantiates the Collection object.
Public widgetCollection As New Collection
' Creates a new Widget and adds it to the widgetCollection.
Private Sub MakeAWidget()
   Dim tempWidget As New Widget()
   widgetCollection.Add(tempWidget)
End Sub
```

The `widgetCollection` collection here organizes and exposes all of the `Widget` objects created through the `MakeAWidget` method. You can retrieve object references to each widget through the index of the collection. The size of the collection is adjusted automatically as each new `Widget` object is added. You can use the **For Each...Next** statements to iterate through the collection. If you want to give the Widget object a key by which it can be retrieved, you can supply a text string as the second parameter of the **Add** method, as described later in this section.

The **New** keyword in the declaration for the variable `widgetCollection` causes a **Collection** object to be created the first time the variable is referred to in code. Because **Collection** is a class, rather than a data type, you must create an instance of it and keep a reference to that instance (object) in a variable.

Like any other object, a **Collection** object is marked for garbage collection when the last variable that contains a reference to it is set to **Nothing** or goes out of scope; all the object references it contains are released when collected. For this reason, the variable `widgetCollection` is declared in the parent class, so that it exists throughout the life of the program.

Inside a Collection Object

A **Collection** object stores each item in an **Object**; thus the list of things you can add to a **Collection** object is the same as the list of things that can be stored in an object variable. This includes standard data types, objects, and arrays, as well as user-defined structures and class instances.

Because the **Collection** object stores each item as an object, **Object** is the type of reference the **Item** property returns. This presents the issue of how to access collection members later. If **Option Strict** is **Off**, you can implicitly convert a reference from the **Collection** to the appropriate type, as shown in this example.

```
Option Strict Off
Dim myString As String = "This is my String"
Dim aString As string
Dim myCollection As New Collection()
myCollection.Add(myString)
aString = myCollection.Item(1)   ' Collection item converted to string.
```

If **Option Strict** is **On,** however, you need to cast from **Object** to the type the collection contains. To obtain a reference from **Item** in this way, you can use the **CType** function to explicitly perform the conversion, as shown below:

```
Option Strict On
Dim myString As String = "This is my String"
Dim aString As String
Dim myCollection As New Collection()
myCollection.Add(myString)
aString = CType(myCollection.Item(1), String)
```

An alternative is to create your own strongly-typed collection. For a discussion on how to do this, see Walkthrough: Creating Your Own Collection Class.

Option Strict Statement

Properties and Methods of the Collection Class

Each **Collection** object includes properties and methods you can use to insert, delete, and retrieve the items in the collection. The following table lists these items.

For information about	See
Adding items to the collection	Add Method
Returning the number of items in the collection	Count Property
Returning an item, by index or by key	Item Property
Deleting an item from the collection, by index or by key	Remove Method

These properties and methods provide only the most basic services for collections. For example, the **Add** method cannot check the type of object being added to a collection, which you might want to do to ensure that the collection contains only one kind of object. You can provide more robust functionality — and additional properties, methods, and events — by creating your own collection class, as described in the walkthrough, Walkthrough: Creating Your Own Collection Class.

The basic services of adding, deleting, and retrieving from a collection depend on keys and indexes. A *key* is a **String** value. It could be a name, a driver's license number, a social security number, or simply an integer converted to a string. The **Add** method allows you to associate a key with an item, as described in Adding, Deleting, and Retrieving Items from a Collection.

An *index* in the **Collection** class is an integer between one (1) and the number of items in the collection. You can control the initial value of an item's index, using the *before* and *after* named parameters, but its value may change as other items are added and deleted. For more information, see the **Add** method.

You can use the index to iterate over the items in a collection. For example, the following code shows two ways to give all the employees in a collection of Employee objects a 10 percent raise, assuming that the variable `employeesCollection` contains a reference to a **Collection** object:

```
Option Strict On
Dim counter As Integer
Dim emp As Employee
For counter = 1 To employeesCollection.Count
   emp = CType(employeesCollection(counter), Employee)
   emp.Rate *= 1.1
Next

 ' Alternative code follows.
Dim emp As Employee
For Each emp In employeesCollection
   emp.Rate *= 1.1
Next
```

> **Note** If you attempt to use **For Each** with a collection that contains items of a different type than the one being iterated, an **ArgumentException** is thrown.

Adding, Deleting, and Retrieving Items from a Collection

The **Collection** class contains built-in functionality to allow you to add, delete and retrieve items. The use of this functionality is demonstrated below.

Adding Items to a Collection

Use the **Add** method to add an item to a collection. The syntax is:

```
object.Add(Item, Key)
```

For example, to add a work order object to a collection of work orders using the work order's ID property as the key, you can write:

```
workordersCollection.Add(woNew, woNew.ID)
```

This assumes that the ID property is a string. If the property is a number (for example, a **Long** integer), use its **.ToString** function to convert it to the **String** value required for keys:

```
workordersCollection.Add(woNew, woNew.ID.ToString)
```

The use of a key is optional. If you do not want to associate a key with the object in your collection, you may add it without a key, as shown below:

```
workordersCollection.Add(woNew)
```

You can use the *before* and *after* arguments to maintain an ordered collection of objects. The member to be added is placed in the collection before or after the member identified by the *before* or *after* argument, respectively. For example, setting *before* equal to 1 inserts an item at the beginning of the collection, because **Collection** objects are one-based, as in the example that follows:

```
workordersCollection.Add(woNew, woNew.ID, 1)
```

Similarly, the *after* argument adds an item after the specified index. The following example adds an item as the third element:

```
workordersCollection.Add(woNew, woNew.ID,,2)
```

You can specify a value for either *before* or *after*, but not both.

Deleting Items from a Collection

Use the **Remove** method to delete an item from a collection. The syntax is:

```
object.Remove(index | key)
```

The *index* argument can either be the position of the item you want to delete, or the item's key. If the key of the third element in a collection is "W017493", you can use either of these two statements to delete it:

```
workordersCollection.Remove(3)
workordersCollection.Remove("W017493")
```

Retrieving Items from a Collection

Use the **Item** property to retrieve specific items from a collection. The syntax is:

```
variable = object.Item(index)
```

As with the **Remove** method, the index can be either the item's position in the collection or the item's key. Using the same

example as for the **Remove** method, either of these statements retrieves the third element in the collection:

```
woCurrent = workordersCollection.Item(3)
woCurrent = workordersCollection.Item("W017493")
```

> **Note** If you use whole numbers as keys, you must use the **.ToString** function to convert them to strings before passing them to the **Add**, **Remove**, or **Item** property. A **Collection** object always assumes that a whole number is an index.

Item Is the Default Property

The **Item** property is the default property for a **Collection** object, so you can omit it when you access an item in a collection. Thus, the previous code examples could also be written as follows:

```
woCurrent = workordersCollection(3)
woCurrent = workordersCollection("W017493")
```

You can also use the **!** member access qualifier to access a member of the collection by its key without qualifying the key with quotation marks or parentheses. Thus the previous example can also be written as follows:

```
woCurrent = workordersCollection!W017493
```

> **Note** Collection objects update their numeric index numbers automatically as you add and delete elements; the numeric index of a given element thus often changes. Therefore, do not save a numeric index value and expect it to retrieve the same element later in your program. Use keys for this purpose.

Obtaining Class Information at Run Time

In some situations, you may need to work with variables defined as type **Object** rather than as more specific object types. Variables defined as **Object** can contain any other type object, such as integers, doubles, or object data types.

In This Section

Determining Object Type
Discusses determining the class an object belongs to.

Calling a Property or Method Using a String Name
Steps you through the process of specifying arguments by name instead of by position when calling a method.

Objects
Covers the fundamentals of object-oriented programming.

Determining Object Type

Generic object variables (that is, variables you declare as **Object**) can hold objects from any class. When using variables of type **Object**, you may need to take different actions based on the class of the object; for example, some objects might not support a particular property or method. Visual Basic .NET provides two means of determining which type of object is stored in an object variable: the **TypeName** function and the **TypeOf...Is** operator.

The **TypeName** function returns a string and is the best choice when you need to store or display the class name of an object, as shown in the following code fragment:

```
    MsgBox(TypeName(Ctrl))
```

The **TypeOfIs** operator is the best choice for testing an object's type, because it is much faster than an equivalent string comparison using **TypeName**. The following code fragment uses **TypeOfIs** within an **If...Then...Else** statement:

```
If TypeOf Ctrl Is Button Then
   MsgBox("The control is a button.")
End If
```

A word of caution is due here. The **TypeOfIs** operator returns **True** if an object is of a specific type, or is derived from a specific type. Almost everything you do with Visual Basic .NET involves objects, which include some elements not normally thought of as objects, such as **Strings** and **Integers**. These objects are derived from and inherit methods from **System.Object**. When passed an **Integer** and evaluated with **Object**, the **TypeOfIs** operator returns **True**. The following example reports that the parameter `InParam` is both an **Object** and an **Integer**:

```
Sub CheckType(ByVal InParam)
' Both If statements evaluate to True when an
' Integer is passed to this procedure.
   If TypeOf InParam Is Object Then
      MsgBox("InParam is an Object")
   End If
   If TypeOf InParam Is Integer Then
      MsgBox("InParam is an Integer")
   End If
End Sub
```

The following example uses both **TypeOfIs** and **TypeName** to determine the type of object passed to it in the `Ctrl` argument. The `TestObject` procedure calls `ShowType` with three different kinds of controls.

To run the example

1. Create a new Windows Forms project and add a **Button** control, a **CheckBox** control, and a **RadioButton** control to the form.
2. From the button on your form, call the `TestObject` procedure.
3. Add the following code to the **Declarations** section of your form:

```
Sub ShowType(ByVal Ctrl As Object)
   'Use the TypeName function to display the class name as text.
   MsgBox(TypeName(Ctrl))
   'Use the TypeOf function to determine the object's type.
   If TypeOf Ctrl Is Button Then
      MsgBox("The control is a button.")
   ElseIf TypeOf Ctrl Is CheckBox Then
      MsgBox("The control is a check box.")
   Else
      MsgBox("The object is some other type of control.")
   End If
End Sub

Protected Sub TestObject()
```

```
'Test the ShowType procedure with three kinds of objects.
   ShowType(Me.Button1)
   ShowType(Me.CheckBox1)
   ShowType(Me.RadioButton1)
End Sub
```

Calling a Property or Method Using a String Name | Performing Multiple Actions on an Object | Obtaining Class Information at Run Time | Object Data Type | TypeOf | TypeName Function | If...Then...Else Statements | String Data Type | Integer Data Type

Calling a Property or Method Using a String Name

In most cases, you can discover the properties and methods of an object at design time, and write code to handle them. In a few cases, however, you may not know about an object's properties and methods in advance, or you may simply want the flexibility of allowing an end user to specify properties or execute methods at run time.

Consider, for example, a client application that evaluates expressions entered by the user by passing an operator to a COM component. Suppose you are constantly adding new functions to the component that require new operators. Using standard object access techniques, you would need to recompile and redistribute the client application before it could use the new operators. To avoid this, you can use the **CallByName** function to pass the new operators as strings, without changing the application.

The **CallByName** function allows you to use a string to specify a property or method at run time. The signature for the **CallByName** function looks like this:

```
Result = CallByName(Object, ProcedureName, CallType, Arguments())
```

The first argument, *Object*, takes the name of the object you want to act upon. The *ProcedureName* argument takes a string containing the name of the method or property procedure to be invoked. The *CallType* argument takes a constant representing the type of procedure to invoke: a method (`Microsoft.VisualBasic.CallType.Method`), a property read (`Microsoft.VisualBasic.CallType.Get`), or a property set (`Microsoft.VisualBasic.CallType.Set`). The *Arguments* argument, which is optional, takes an array of type **Object** containing any arguments to the procedure.

You can use **CallByName** with classes in your current solution, but it is most often used to access COM objects or objects from .NET assemblies.

Suppose you add a reference to an assembly that contains a class named `MathClass`, which has a new function named `SquareRoot`, as shown in the following code:

```
Class MathClass
   Function SquareRoot(ByVal X As Double) As Double
      Return Math.Sqrt(X)
   End Function
   Function InverseSine(ByVal X As Double) As Double
      Return Math.Atan(X / Math.Sqrt(-X * X + 1))
   End Function
   Function Acos(ByVal X As Double) As Double
      Return Math.Atan(-X / Math.Sqrt(-X * X + 1)) + 2 * Math.Atan(1)
   End Function
End Class
```

Your application could use text box controls to control the method will be called and its arguments. For example, if `TextBox1` contains the expression to be evaluated, and `TextBox2` is used to enter the name of the function, you can use the following code to invoke the `SquareRoot` function on the expression in `TextBox1`:

```
Private Sub CallMath()
   Dim Math As New MathClass()
   Me.TextBox1.Text = CStr(CallByName(Math, Me.TextBox2.Text, _
      Microsoft.VisualBasic.CallType.Method, TextBox1.Text))
End Sub
```

If you enter "64" in `TextBox1`, "SquareRoot" in `TextBox2`, and then call the `CallMath` procedure, the square root of the number in `TextBox1` is evaluated. The code in the example invokes the `SquareRoot` function (which takes a string containing the expression to be evaluated as a required argument) and returns "8" in `TextBox1` (the square root of 64). Of course, if the user enters an invalid string in `TextBox2`, if the string contains the name of a property instead of a method, or if the method had an additional required argument, a run-time error occurs. You need to add robust error-handling code when you use **CallByName** to anticipate these or any other errors.

> **Note** While the **CallByName** function may be useful in some situations, you need to weigh its usefulness against the performance implications — using **CallByName** to invoke a procedure is slightly slower than a late-bound call. If you are invoking a function that is called repeatedly, such as inside a loop, **CallByName** can have a severe effect on performance.

Understanding Classes

Classes are important in object-oriented programming because they allow you to group related items as a unit as well as control their visibility and accessibility to other procedures. Classes also can inherit and reuse code defined in other classes.

Classes: Blueprints for Objects

Classes are symbolic representations of objects; they describe the properties, fields, methods, and events that make up objects in the same way that blueprints describe the items that make up a building. Just as a blueprint can be used to create multiple buildings, a single class can be used to create as many objects as necessary. Just as a blueprint defines which parts of a building are accessible to people who use the building, so too can classes control user access to object items through encapsulation.

Classes and Objects

The terms "class" and "object" are sometimes used interchangeably, but in fact, classes describe the *structure* of objects, while objects are usable *instances* of classes. Each instance is an exact yet distinct copy of its class. Because an object is an "instance" of a class, the act of creating an object is called *instantiation*.

Using the blueprint analogy, a class is a blueprint, and an object is a building based on that blueprint. For the most part, changing the data in one object does not change the data in any other object. (The exception is *shared members,* class members declared with the **Shared** modifier, which exist independently of specific instances of a class.)

Encapsulation

Encapsulation is the ability to contain and control the access to a group of associated items. Classes provide one of the most common ways to encapsulate items. In the example below, the `BankAccount` class encapsulates the methods, fields, and properties that describe a bank account. Without encapsulation, you would need to declare separate procedures and variables to store and manage information for the bank account, and it would be difficult to work with more than one bank account at a time. Encapsulation lets you use the data and procedures in the `BankAccount` class as a unit. You can work with multiple bank accounts at the same time without confusion because each account is represented by a unique instance of the class.

Encapsulation also allows you to control how the data and procedures are used. You can use access modifiers, such as **Private** or **Protected**, to prevent outside procedures from executing class methods or reading and modifying data in properties and fields. You should declare internal details of a class as **Private** to prevent them from being used outside your class; this technique is called *data hiding*. In the `BankAccount` class, customer information such as account balance is protected this way. One of the basic rules of encapsulation is that class data should be modified or retrieved only via **Property** procedures or methods. Hiding the implementation details of your classes prevents them from being used in undesired ways, and lets you modify such items later without risk of compatibility problems. For example, later versions of the `BankAccount` class listed below could change the data type of the `AccountBalance` field without danger of breaking applications that rely on this field having a specific data type.

Inheritance

Like Visual Basic .NET structures, classes let you define data types that encapsulate a group of related items. Unlike structures, however, Visual Basic .NET classes can inherit and extend the characteristics of other classes. Classes that serve as a basis for new classes are called *base classes*. Classes derived from base classes are called *derived classes*. Derived classes inherit all the fields, properties, methods, and events defined in the base class. This means you can develop and debug a class once, and then reuse it as the basis for other classes.

The following example defines a base class that represents a generic bank account, and a specific class that inherits the properties of the base class but is customized to describe a checking account:

```
Class BankAccount
   Private AccountNumber As String
   Private AccountBalance As Decimal
   Private HoldOnAccount As Boolean = False
   Public Sub PostInterest()
      ' Add code to calculate the interest for this account.
   End Sub
   ReadOnly Property Balance() As Decimal
      Get
         Return AccountBalance 'Returns the available balance.
      End Get
   End Property
End Class

Class CheckingAccount
   Inherits BankAccount
   Sub ProcessCheck()
      ' Add code to process a check drawn on this account.
```

```
    End Sub
End Class
```

For more information about inheritance, see Inheritance Basics.

Shared Members

By default, class data is specific to each instance of the class, but there may be occasions when you want a single data item to be shared among all objects created from a class. In such cases, you can use the **Shared** modifier to cause a variable to share the same value in all instances of a class. (Shared members are sometimes referred to as "static members" in other programming languages.) You can call shared methods directly using a class name without first creating an instance of the class.

For more information about shared members, see Shared Members.

Shadowing

Derived classes can use the **Shadows** keyword to declare a member with the same name as an inherited member. Shadowed members do not need to be the same data type as the member being shadowed. For example, a property can shadow a variable of type **Integer**.

For more information about shared members, see Shadowing.

Creating and Using Objects | Structures and Classes | Inheritance | Inheritance Basics | Shared Members | Shadowing | Shadows | Shared

Walkthrough: Defining Classes

This walkthrough demonstrates how to use class modules to define classes, from which you can then create objects. It also shows you how to create properties and methods for the new class, and demonstrates how objects are initialized.

To define a class

1. Open a new Windows Application project by clicking **New** on the **File** menu, and then clicking **Project**. The **New Project** dialog box appears.
2. Select Windows Application from the list of Visual Basic project templates. The new project is displayed.
3. Add a new class to the project by clicking **Add Class** on the **Project** menu. The **Add New Item** dialog box appears.
4. Name the new module `StateInfo.vb`, and then click **Open**. The code for the new class is displayed:

```
Public Class StateInfo
End Class
```

   Note You can use the Visual Studio .NET code editor to add a class to your startup form by typing the **Class** keyword followed by the name of the new class. The code editor provides a corresponding **End Class** statement for you.

5. To simplify access to the registry classes, add an **Imports** statement to the top of the source code containing the class statement:

```
Imports Microsoft.Win32
```

6. Define three private fields for the class by placing the following code between the **Class** and **End Class** statements:

```
   Private pVal As String ' Holds the LastFile property value.
   Private KeyName As String ' Holds the name of the registry key.
   Private SubKeyName As String ' Holds the name of the subkey.
```

   These three fields are declared as **Private**, and can be used only from within the class. You can make fields accessible from outside a class by using access modifiers that provide greater access, such as **Public**.

7. Define a property for the class by adding the following code:

```
Public Property LastFile() As String
   Get ' Retrieves the property value.
      Return pVal
   End Get
   Set(ByVal Value As String)
      pVal = Value
   End Set
End Property
```

8. Define methods for the class by adding the following code:

```
Sub SaveStateInfo()
'  Save the current value of the LastFile property to the registry.
   Dim aKey As RegistryKey
'  Create a key if it does not exist.
   aKey = Registry.CurrentUser.CreateSubKey(KeyName)
'  Save the property value to the registry.
   aKey.SetValue(SubKeyName, pVal)
End Sub

Sub GetStateInfo()
'  Restore the property value LastFile from the
'  value stored in the registry.
```

```
   Dim aKey As Object
   Dim myRegKey As RegistryKey = Registry.CurrentUser
   Try
'  This call goes to the Catch block if the registry key is not set.
   myRegKey = myRegKey.OpenSubKey(KeyName)
      Dim oValue As Object = myRegKey.GetValue(SubKeyName)
         pVal = CStr(oValue)
   Catch
      pVal = "" ' Set to default if key value cannot be read.
   End Try
End Sub
```

9. Define a parameterized constructor for the new class by adding a procedure named **Sub New**:

```
Sub New(ByVal RegistryKeyName As String, _
        ByVal RegistrySubKeyName As String)
'  Save the names of the registry key and subkey in two fields.
   KeyName = RegistryKeyName
   SubKeyName = RegistrySubKeyName
'  Restore the value of the LastFile property from the registry.
   MyClass.GetStateInfo()
End Sub
```

The **Sub New** constructor is called automatically when an object based on this class is created. This constructor sets the value of the fields that hold the registry key and subkey names, and calls a procedure that restores the value of the `LastFile` property from the registry.

> **Note** This walkthrough uses the registry to store state information for the class. Information stored in the registry is available to other applications and users, and therefore it should not be used to store security, or critical application information.

10. Define a **Finalize** destructor for the class by adding a procedure called `Finalize`:

```
Protected Overrides Sub Finalize()
'  Save the value of the LastFile property to the registry
'  when the class loses scope.
   SaveStateInfo()
   MyBase.Finalize() ' Call Finalize on the base class.
End Sub
```

The **Finalize** destructor saves the value stored in the property to the registry after the class loses scope.

To create a button to test the class

1. Change the startup form to design mode by right-clicking its name in the Solution Explorer, and then clicking **View Designer**. The startup form for Windows Application projects is named Form1.vb by default. The main form appears.
2. Add a button to the main form and double-click it to display the code for the **Button1_Click** event handler. Add the following code to call the test procedure:

```
'  Create an instance of the class and pass the registry key
'  names to the Sub New constructor.
   Dim SI As New StateInfo("Software\StateInfo", "PropertyValue")
'  Display the value of the property if it has been restored.
   If Len(SI.LastFile) > 1 Then
      MsgBox("The value of the property LastFile is: " _
             & SI.LastFile)
   Else
      MsgBox("The LastFile property has not been set.")
   End If
   SI.LastFile = "C:\BinaryFile.txt" ' Set the property.
```

```
'  Ask the object to save the property value to the registry.
   SI.SaveStateInfo()
```

To run your application

1. Run your application by pressing F5. The application appears.
2. Click the button on the form to call the test procedure. The first time you do so, a message is displayed stating that the `LastFile` property has not been set.
3. Click **OK** to dismiss the message box. The **Button1_Click** procedure sets the value of the `LastFile` property and calls the **SaveState** method. Even if **SaveState** were not called explicitly from **Button1_Click**, it would be called automatically by the **Finalize** method after the startup form is closed.
4. Click the button a second time. The message "The value of the property LastFile is C:\BinaryFile.txt" is displayed.
5. Close the main form and then restart the program by pressing F5. An object based on the class is created, and its **Sub New** constructor calls the **GetStateInfo** procedure that restores the property value from the registry. The message "The value of the property LastFile is C:\BinaryFile.txt" is displayed again when you click the button.

See Also

Classes vs. Standard Modules | Class Properties, Fields, and Methods | Adding Events to a Class | Imports Statement

Classes vs. Standard Modules

Both classes and modules are reference types that encapsulate items defined within, but they differ in how these items are accessed from other procedures.

The primary difference between classes and modules is that classes can be instantiated and standard modules cannot. Because there is never more than one copy of a standard module's data, when one part of your program changes a public variable in a standard module, any other part of the program gets the same value if it subsequently reads that variable. Class data, on the other hand, exists separately for each instantiated object. Another difference is that unlike standard modules, classes can implement interfaces.

Classes and modules also employ different scope for their members. Members defined within a class are scoped within a specific instance of the class, and exist only for the lifetime of the object. The practical result is that, to access class members from outside a class, you must use only fully qualified names; for example, `Object.Member`. Members declared within a standard module, on the other hand, are shared by default, and are scoped to the declaration space of the standard module's containing namespace. This means that public variables in a standard module are effectively global variables because they are visible from anywhere in your project, and they exist for the life of the program. Unlike class members, members of standard modules are implicitly shared and cannot use the Shared keyword.

Understanding Classes | Structures and Classes | Shared Members | Ways to Implement Component Functionality | Shared

Object Lifetime: How Objects Are Created and Destroyed

Objects begin life when an instance of a class is created using the **New** keyword. New objects often require initialization tasks to be performed before they are used for the first time. Common initialization tasks include opening files, connecting to a database, and reading the values of registry keys. Microsoft Visual Basic .NET controls the initialization of new objects using procedures called constructors.

Objects end life after they leave scope and are released by the common language runtime (CLR). Visual Basic .NET controls the release of system resources using procedures called *destructors*. Together, *constructors* (special methods that allow control over initialization) and destructors support the creation of robust and predictable class libraries.

Sub New and Sub Finalize

The **Sub New** and **Sub Finalize** procedures in Visual Basic .NET initialize and destroy objects; they replace the **Class_Initialize** and **Class_Terminate** methods used in previous versions of Visual Basic. Unlike **Class_Initialize**, the **Sub New** constructor can run only once when a class is created, and it cannot be called explicitly anywhere other than in the first line of code in another constructor from either the same class or from a derived class. Furthermore, the code in the **Sub New** method always runs before any other code in a class. Visual Basic .NET implicitly creates a **Sub New** constructor at run time if you do not explicitly define a **Sub New** procedure for a class.

Before releasing objects, the CLR automatically calls the **Finalize** method for objects that define a **Sub Finalize** procedure. The **Finalize** method can contain code that needs to execute just before an object is destroyed, such as closing files and saving state information. There is a slight performance penalty for executing **Sub Finalize**, so you should define a **Sub Finalize** method only when you need to release objects explicitly.

The **Finalize** destructor is a protected method that can be called only from the class it belongs to, or from derived classes. The system calls **Finalize** automatically when an object is destroyed, so you should not explicitly call **Finalize** from outside of a derived class's **Finalize** implementation. Unlike **Class_Terminate**, which executed as soon as an object was set to nothing, there is usually a delay between when an object loses scope and when Visual Basic .NET calls the **Finalize** destructor. Visual Basic .NET allows for a second kind of destructor, named **Dispose**, which can be explicitly called at any time to release resources immediately.

IDisposable Interface

Class instances often control resources not managed by the CLR, such as Windows handles and database connections. To supplement garbage collection, your classes can provide a mechanism to actively manage system resources if they implement the **IDisposable** interface. **IDisposable** has one method, **Dispose**, which clients should call when they finish using an object. You can use the implementation of **Dispose** to release resources and perform tasks such as closing files and database connections. Unlike the **Finalize** destructor, the **Dispose** method is not called automatically. Clients of a class must explicitly call **Dispose** when you want to release resources.

Garbage Collection and the Finalize Destructor

The .NET Framework uses a system called *reference-tracing garbage collection* that periodically releases unused resources. Previous versions of Visual Basic use a different system called *reference counting* to manage resources. Although both systems perform the same function automatically, there are a few important differences.

The CLR periodically destroys objects when the system determines that such objects are no longer needed. Objects are released more quickly when system resources are in short supply, and less frequently otherwise. The delay between when an object loses scope and when the CLR releases it means that, unlike with objects in previous versions of Visual Basic, you cannot determine exactly when the object will be destroyed. In such a situation, objects are said to have *non-deterministic lifetime*. In most cases, non-deterministic lifetime does not change how you write applications, as long as you remember that the **Finalize** destructor may not execute immediately when an object loses scope.

Another difference between the garbage collection systems involves the use of **Nothing**. To take advantage of reference counting, programmers using previous versions of Visual Basic sometimes assign **Nothing** to object variables in order to release the references those variables hold. If the variable holds the last reference to the object, the object's resources are released immediately. In Visual Basic .NET, while there may be cases in which this procedure is still valuable, performing it never causes the referenced object to release its resources immediately. The only time you should set a variable to **Nothing** is when its lifetime is long relative to how long it takes the garbage collector to detect orphaned objects.

Using Constructors and Destructors

Constructors and destructors control the creation and destruction of objects.

To create a constructor for a class, create a procedure named **Sub New** anywhere in the class definition. To create a parameterized constructor, specify the names and data types of arguments to **Sub New** just as you would specify arguments for any other procedure, as in the following code:

```
Sub New(ByVal sString As String)
```

Constructors are frequently overloaded, as in the following code:

`Sub New(ByVal sString As String, iInt As Integer)`

When you define a class derived from another class, the first line of a constructor must be a call to the constructor of the base class, unless the base class has an accessible constructor that takes no parameters. A call to the base class containing the above constructor, for example, would be `MyBase.New(sString)`. Otherwise, `MyBase.New` is optional, and the Visual Basic .NET runtime calls it implicitly.

After writing code to call the parent object's constructor, you can add any additional initialization code to the **Sub New** procedure. **Sub New** can accept arguments when called as a parameterized constructor. These parameters are passed from the procedure calling the constructor; for example, `Dim AnObject As New ThisClass(X)`.

The following code example shows how to use **Dispose** and **Finalize** to release resources:

```
' Design pattern for a base class.
Public Class Base
    Implements IDisposable
    ' Implement IDisposable.
    Public Overloads Sub Dispose() Implements IDisposable.Dispose
        Dispose(True)
        GC.SuppressFinalize(Me)
    End Sub

    Protected Overridable Overloads Sub Dispose(ByVal disposing As Boolean)
        If disposing Then
            ' Free other state (managed objects).
        End If
        ' Free your own state (unmanaged objects).
        ' Set large fields to null.
    End Sub

    Protected Overrides Sub Finalize()
        ' Simply call Dispose(False).
        Dispose(False)
    End Sub
End Class

' Design pattern for a derived class.
Public Class Derived
    Inherits Base

    Protected Overloads Overrides Sub Dispose(ByVal disposing As Boolean)
        If disposing Then
            ' Release managed resources.
        End If
        ' Release unmanaged resources.
        ' Set large fields to null.
        ' Call Dispose on your base class.
        MyBase.Dispose(disposing)
    End Sub
    ' The derived class does not have a Finalize method
    ' or a Dispose method with parameters because it inherits
    ' them from the base class.
End Class
```

The following example shows a common design pattern for using the **Dispose** destructor:

```
Dim con As Connection, rs As RecordSet
Try
   con = New Connection("xyz")
   rs = New RecordSet(con, "MyTable")
   ' Use the connection if successful.
Finally
' Call the Dispose method when done with any created objects.
If Not con Is Nothing Then
      con.Dispose()
   End If
   If Not rs Is Nothing Then
      rs.Dispose()
   End If
End Try
```

The next example creates an object using a parameterized constructor, and calls destructors when the object is no longer needed:

```
Sub TestConstructorsAndDestructors()
   Dim X As Integer = 6
   Dim AnObject As New ThisClass(X)
   ' Place statements here that use the object.
   AnObject.DoSomething()
   ' Test the parameterized constructor.
   MsgBox("The value of ThisProperty after being initialized " & _
          " by the constructor is " & AnObject.ThisProperty)
   ' Run the Dispose method when you are done with the object.
   AnObject.Dispose()
End Sub

   Public Class BaseClass
      Sub New()
         MsgBox("The base class is initializing with Sub New.")
      End Sub

      Protected Overrides Sub Finalize()
         MsgBox("The base class is destroying objects with Sub Finalize.")
         ' Place final cleanup tasks here.
         MyBase.Finalize()
      End Sub
   End Class

   Public Class ThisClass
      Inherits BaseClass
      Implements IDisposable ' Implements the Dispose method of IDisposable.
      Private m_PropertyValue  As Integer

      Sub New(ByVal SomeValue As Integer)
         MyBase.New() ' Call MyBase.New if this is a derived class.
         MsgBox("Sub New is initializing the class ThisClass.")
         ' Place initialization statements here.
         m_PropertyValue  = SomeValue
      End Sub

      Property ThisProperty() As Integer
         Get
            ThisProperty = m_PropertyValue
         End Get
         Set(ByVal Value As Integer)
            m_PropertyValue  = Value
         End Set
      End Property

      Sub DoSomething()
         ' Place code here that does some task.
      End Sub
```

```
        Protected Overrides Sub Finalize()
           MsgBox("Finalize is destroying objects in ThisClass.")
           ' Place final cleanup tasks here.
           MyBase.Finalize()
        End Sub

        Overridable Sub Dispose() Implements IDisposable.Dispose
           MsgBox("The ThisClass is running Dispose.")
        End Sub
     End Class
```

When you run this example, the class `ThisClass` calls the **Sub New** constructor of the class `BaseClass`. After the constructor in the base class is finished, the class `ThisClass` runs the remaining statements in **Sub New** that initialize a value for the property `ThisProperty`.

When the class is no longer needed, the **Dispose** destructor is called in `ThisClass`.

If you originally created the instance of `ThisClass` from a form, nothing will seem to happen until you close the form. At that point, the **Finalize** destructor runs in the class `ThisClass` and finally in the class `BaseClass`.

Class Properties, Fields, and Methods

In general, fields and properties represent information about an object, whereas methods represent actions an object can take.

The following topics describe the mechanisms for adding properties, fields, and methods to your classes, and address issues associated with these items.

In This Section

Adding Fields and Properties to a Class
Provides information on declaring fields and properties.
Properties and Property Procedures
Explains how **Property** procedures work, and how to implement common property types.
Property Procedures vs. Fields
Helps you decide when to use fields to store data in a class, and when properties are a better choice.
Class Methods
Discusses the public procedures you add to your class.
Properties vs. Methods
Helps you decide whether your desired functionality is best implemented as a property or a method.
Default Properties
Discusses properties that are used when no specific property is named.
Overloaded Properties and Methods
Covers how to define multiple properties or methods that have the same name, but work with different data types.
Overriding Properties and Methods
Discusses redefining an inherited property or method.
Object Management with Collections
Provides information on using collections to store and retrieve objects.

Demonstrates how to declare and use events and delegates.

Adding Fields and Properties to a Class

You can use both fields and properties to store information in an object. Although fields and properties are almost indistinguishable from a client-application perspective, they are declared differently within a class. Whereas fields are simply public variables that a class exposes, properties use **Property** procedures to control how values are set or returned.

To add a field to a class

- Declare a public variable in the class definition, as in the following code:

```
Class ThisClass
   Public ThisField As String
End Class
```

To add a property to a class

1. Declare a local variable within the class to store the property value. This step is necessary because properties do not allocate any storage on their own. To protect their values from direct modification, variables used to store property values should be declared as **Private**.
2. Preface property declarations with modifiers, such as **Public** and **Shared**, as appropriate. Use the **Property** keyword to declare the property name, and declare the data type that the property stores and returns.
3. Define **Get** and **Set** property procedures within the property definition. **Get** property procedures are used to return the value of a property and are roughly equivalent to functions in syntax. They accept no arguments and can be used to return the value of private local variables declared within the class used to store the property value. **Set** property procedures are used to set the value of a property; they have a parameter, usually called `Value`, with the same data type as the property itself. Whenever the value of the property is changed, `Value` is passed to the **Set** property procedure, where it can be validated and stored in a local variable.
4. Terminate **Get** and **Set** property procedures with **End Get** and **End Set** statements as appropriate.
5. Terminate the property block with an **End Property** statement.

> **Note** If you are working within the Visual Studio integrated development environment (IDE), you can direct it to stub out empty **Get** and **Set** property procedures. Type **Property** *PropName* **As** *DataType* (where *PropName* is the name of your property, and *DataType* is a specific data type, such as **Integer**), and the property procedures appear in the Code editor.

The following example declares a property in a class:

```
Class ThisClass
   Private m_PropVal As String
   Public Property One() As String
      Get
         Return m_PropVal ' Return the value stored in the local variable.
       ' Optionally, you can use the syntax One = PropVal to return
       ' the property value.
      End Get
      Set(ByVal Value As String)
         m_PropVal = Value ' Store the value in a local variable.
      End Set
   End Property
End Class
```

When you create an instance of `ThisClass` and set the value of the property `One`, the **Set** property procedure is called and the value is passed in the `Value` parameter, which is stored in a local variable named `m_PropVal`. When the value of this property is retrieved, the **Get** property procedure is called like a function and returns the value stored in the local variable `m_PropVal`.

Properties and Property Procedures

You can use both properties and fields to store information in an object. Whereas fields are simply public variables, properties use property procedures to control how values are set or returned. Property procedures are blocks of code declared within property definitions that allow you to execute code when a property value is set or retrieved. Visual Basic .NET has two types of property procedures: **Get** property procedures for retrieving a property value, and **Set** property procedures for assigning a value to a property. For example, a property that stores the balance of a bank account might use code in a **Get** property procedure to post interest and check for service fees before returning the available balance. The **Set** property procedure for the available balance could provide validation code to prevent the balance from being updated incorrectly. In short, property procedures allow an object to protect and validate its own data.

The following code fragment compares how fields and properties validate values:

```
Protected Sub TestFieldsAndProperties()
   ' Assume, for this example, that the only valid values for
   ' the field and property are numbers less than 10.
   Dim NewClass As New ThisClass()

   ' Test data validation.
   NewClass.ThisField = 36   ' Works because there is no data validation.
   MsgBox("ThisField = " & NewClass.ThisField)   ' Will print 36.

   ' The attempt to set the field to a value greater than 10 will silently fail.
   NewClass.ThisProperty = 36
   ' The next statement will print the old value of 0 instead.
   MsgBox("ThisProperty = " & NewClass.ThisProperty)
End Sub

Public Class ThisClass
   Public ThisField As Integer   ' This is a field.
   Private m_PropertyValue   As Integer = 0   ' Used for Property Set operations.
   Public Property ThisProperty() As Integer   ' This is a property.
      Get
         Return m_PropertyValue
      End Get
      Set(ByVal Value As Integer)
         ' Only allow Set operation for values less than 10.
         If Value < 10 Then m_PropertyValue = Value
      End Set
   End Property
End Class
```

The procedure `TestFieldsAndProperties` creates an instance of the class and sets and retrieves the values of fields and properties. For the sake of this example, it is assumed that the only valid values are numbers less than 10. Because there is no way to validate values assigned to fields, setting the field to value 36 is allowed. The property, however, only performs assignment for numbers less than 10, so the attempt to set it to 36 is ignored.

Read-Only and Write-Only Properties

Most properties have both **Get** and **Set** property procedures to allow you to both read and modify the value stored inside. However, you can use the **ReadOnly** or **WriteOnly** modifiers to restrict properties from being modified or read. Read-only properties cannot have **Set** property procedures; they are useful for items that you want to expose but not allow to be modified. For example, you could use a read-only property to provide the processor speed of a computer. Write-only properties cannot have **Get** property procedures and are useful for data that you want to store but not expose to other objects. For example, a write-only property could be used to store a password.

> **Note** Previous versions of Visual Basic support **Let** property procedures for use when assigning objects to properties. Visual Basic .NET eliminates the need for **Let** property procedures because object assignment is handled like any other kind of assignment.

See Also

Get Statement | Set Statement | Property Procedures | Property Procedures vs. Fields | ReadOnly | WriteOnly

Property Procedures vs. Fields

Properties and fields both store and retrieve information in an object. Their similarity can make it difficult to determine which is a better programming choice in a given case.

Use property procedures when:

- You need to control when and how a value is set or retrieved.
- The property has a well-defined set of values that need to be validated.
- Setting the value causes some perceptible change in the object's state, such as a visible property.
- Setting the property causes changes to other internal variables or to the values of other properties.
- A set of steps must be performed before the property can be set or retrieved.

Use fields when:

- The value is of a self-validating type. For example, an error or automatic data conversion occurs if a value other than **True** or **False** is assigned to a **Boolean** variable.
- Any value in the range supported by the data type is valid. This is true of many properties of type **Single** or **Double**.
- The property is a **String** data type, and there is no constraint on the size or value of the string.

See Also

Classes vs. Standard Modules | Properties and Property Procedures | Data Types (Conceptual) | Data Types (Language Reference)

Class Methods

The methods of a class are just **Sub** or **Function** procedures declared within the class. For example, to create a `Withdrawal` method for a class named `Account`, you could add this **Public** function to the class module:

```
Public Function WithDrawal(ByVal Amount As Decimal, _
      ByVal TransactionCode As Byte) As Double
   ' Add code here to perform the withdrawal,
   ' return a transaction code,
   ' or to raise an overdraft error.
End Function
```

Shared Methods

Shared methods can be invoked directly from a class variable without first creating an instance of the class. Shared methods are useful when you do not want a method to be associated with a specific instance of a class. Shared methods cannot be declared using the **Overridable**, **NotOverridable**, or **MustOverride** modifiers. Methods declared in modules are implicitly shared and cannot explicitly use the **Shared** modifier.

Example

```
   Class ShareClass
      Shared Sub SharedSub()
         MessageBox.Show("Shared method.")
      End Sub
   End Class

Sub Test()
   ' Create an object variable, but not an instance.
   Dim S As ShareClass
   S.SharedSub ' Call the method.
End Sub
```

Protecting Implementation Details

Utility procedures that are used internally by a class should be declared as **Private**, **Protected**, or **Friend**. Restricting the accessibility of such methods prevents them from being used by other developers, and allows you to make future changes without affecting code that uses the objects.

Hiding the details of an object's implementation is another facet of *encapsulation*. Encapsulation allows you to enhance the performance of methods, or completely change the way a method is implemented, without having to change code that uses the method.

See Also

Adding Events to a Class | Properties vs. Methods | Procedures | Shared Members | Overridable | NotOverridable | MustOverride | Shared | Public | Private | Protected | Friend

Properties vs. Methods

Properties and methods are similar in that both are implemented as procedures that accept arguments. In general, properties store data for an object, and methods are actions an object can be asked to perform. Some object characteristics are obviously properties, such as **Name**, and some are obviously methods, such as **Move** and **Show**. In other cases, it is not obvious which class members should be properties and which should be methods. For example, the **Item** method of a collection class stores and retrieves data and can be implemented as an indexed property. On the other hand, it is also reasonable to implement **Item** as a method.

Property Syntax vs. Method Syntax

One way to decide how to implement a class member is to consider how you want it to be used. Although the syntax for retrieving information from a parameterized property is almost identical to the syntax used with a method implemented as a function, the syntax for modifying such a value is slightly different. For example, if you implement the member of a class as a property, the following syntax describes how it would be used:

```
ThisObject.ThisProperty(Index) = NewValue
```

If you implement the class member as a method, the value being modified must be an argument. The following code fragment describes equivalent syntax usage:

```
ThisObject.ThisProperty(Index,NewValue)
```

Error Messages

Another factor to consider when choosing how to implement a class member is what kind of messages will be generated when your class is used incorrectly. If someone accidentally attempts to assign a value to a read-only property, a different error message is returned than in response to a similar call to a method. Correctly implemented class members return error messages that are easier to interpret.

See Also

Adding Fields and Properties to a Class | Class Methods | Item Property

Default Properties

A property that accepts arguments can be declared as the default property for a class. A *default property* is the property that Microsoft Visual Basic .NET will use when no specific property has been named for an object. Default properties are useful because they allow you to make your source code more compact by omitting frequently used property names.

The best candidates for default properties are those properties that accept parameters and that you think will be used the most often. For example, the **Item** property is a good choice for the default property of a collection class because it is used frequently.

The following rules apply to default properties:

- A type can have only one default property, including properties inherited from a base class. There is one exception to this rule. A default property defined in a base class can be shadowed by another default property in a derived class.
- If a default property from a base class is shadowed by a non-default property in a derived class, the default property is still accessible using default property syntax.
- A default property may not be **Shared** or **Private**.
- If an overloaded property is a default property, all overloaded properties with that same name must also specify **Default**.
- Default properties must accept at least one argument.

Example

The following example declares a property that contains an array of strings as the default property for a class:

```
Class Class2
   ' Define a local variable to store the property value.
   Private PropertyValues As String()
   ' Define the default property.
   Default Public Property Prop1(ByVal Index As Integer) As String
      Get
         Return PropertyValues(Index)
      End Get
      Set(ByVal Value As String)
         If PropertyValues Is Nothing Then
            ' The array contains Nothing when first accessed.
            ReDim PropertyValues(0)
         Else
            ' Re-dimension the array to hold the new element.
            ReDim Preserve PropertyValues(UBound(PropertyValues) + 1)
         End If
         PropertyValues(Index) = Value
      End Set
   End Property
End Class
```

Accessing Default Properties

You can access default properties using abbreviated syntax. For example, the following code fragment uses both standard and default property syntax:

```
Dim C As New Class2()
' The first two lines of code access a property the standard way.
C.Prop1(0) = "Value One"    ' Property assignment.
MessageBox.Show(C.Prop1(0)) ' Property retrieval.

' The following two lines of code use default property syntax.
C(1) = "Value Two"     ' Property assignment.
MessageBox.Show(C(1))  ' Property retrieval.
```

Default | Default Properties for Your Components | Upgrade Recommendation: Resolve Parameterless Default Properties | Default Property Changes in Visual Basic

Overloaded Properties and Methods

Overloading is the creation of more than one procedure, instance constructor, or property in a class with the same name but different argument types.

Overloading is especially useful when your object model dictates that you employ identical names for procedures that operate on different data types. For example, a class that can display several different data types could have `Display` procedures that look like this:

```
Overloads Sub Display(ByVal theChar As Char)
' Add code that displays Char data.
End Sub
Overloads Sub Display(ByVal theInteger As Integer)
' Add code that displays Integer data.
End Sub
Overloads Sub Display(ByVal theDouble As Double)
' Add code that displays Double data.
End Sub
```

Without overloading, you would need to create distinct names for each procedure, even though they do the same thing, as shown next:

```
Sub DisplayChar(ByVal theChar As Char)
' Add code that displays Char data.
End Sub
Sub DisplayInt(ByVal theInteger As Integer)
' Add code that displays Integer data.
End Sub
Sub DisplayDouble(ByVal theDouble As Double)
' Add code that displays Double data.
End Sub
```

Overloading makes it easier to use properties or methods because it provides a choice of data types that can be used. For example, the overloaded `Display` method discussed previously can be called with any of the following lines of code:

```
Display("9"C) ' Call Display with a literal of type Char.
Display(9)    ' Call Display with a literal of type Integer.
Display(9.9R) ' Call Display with a literal of type Double.
```

At run time, Visual Basic .NET calls the correct procedure based on the data types of the parameters you specify.

Note Overloading, overriding, and shadowing are similar concepts that can be easy to confuse. See Introduction to Objects in Visual Basic for more information.

Overloading Rules

You create an overloaded member for a class by adding two or more properties or methods with the same name. Except for overloaded derived members, each overloaded member must have different parameter lists, and the following items cannot be used as a differentiating feature when overloading a property or procedure:

- Modifiers, such as **ByVal** or **ByRef**, that applies to a member, or parameters of the member.
- Names of parameters
- Return types of procedures

The **Overloads** keyword is optional when overloading, but if any overloaded member uses the **Overloads** keyword, then all other overloaded members with the same name must also specify this keyword.

Derived classes can overload inherited members with members that have identical parameters and parameter types, a process known as *shadowing by name and signature*. If the **Overloads** keyword is used when shadowing by name and signature, the derived classes implementation of the member will be used instead of the implementation in the base class, and all other overloads for that member will be available to instances of the derived class.

If the **Overloads** keyword is omitted when overloading an inherited member with a member that has identical parameters and

parameter types, then the overloading is called *shadowing by name*. Shadowing by name replaces the inherited implementation of a member, and makes all other overloads unavailable to instances of the derived class, and its decedents.

The **Overloads** and **Shadows** modifiers cannot both be used with the same property or method.

Example

The following example creates overloaded methods that accept either a **String** or **Decimal** representation of a dollar amount and return a string containing the sales tax.

To use this example to create an overloaded method

1. Open a new project and add a class named `TaxClass`.
2. Add the following code to the `TaxClass` class.

```
Public Class TaxClass
   Overloads Function TaxAmount(ByVal decPrice As Decimal, _
        ByVal TaxRate As Single) As String
     TaxAmount = "Price is a Decimal. Tax is $" & _
        (CStr(decPrice * TaxRate))
  End Function

  Overloads Function TaxAmount(ByVal strPrice As String, _
        ByVal TaxRate As Single) As String
     TaxAmount = "Price is a String. Tax is $" & _
        CStr((CDec(strPrice) * TaxRate))
   End Function
End Class
```

3. Add the following procedure to your form.

```
Sub ShowTax()
   Const TaxRate As Single = 0.08   ' 8% tax rate
   Dim strPrice As String = "64.00"   ' $64.00 Purchase as a String.
   Dim decPrice As Decimal = 64   ' $64.00 Purchase as a Decimal.
   Dim aclass As New taxclass()
    'Call the same method with two diferent kinds of data.
   MessageBox.Show(aclass.TaxAmount(strPrice, TaxRate))
   MessageBox.Show(aclass.TaxAmount(decPrice, TaxRate))
End Sub
```

4. Add a button to your form and call the `ShowTax` procedure from the `Button1_Click` event of the button.
5. Run the project and click the button on the form to test the overloaded `ShowTax` procedure.

At run time, the compiler chooses the appropriate overloaded function that matches the parameters being used. When you click the button the overloaded method is called first with a `Price` parameter that is a string and the message: "Price is a String. Tax is $5.12" is displayed. `TaxAmount` is called with a Decimal value the second time and the message, "Price is a Decimal. Tax is $5.12" is displayed.

Overriding Properties and Methods

Derived classes inherit properties and methods defined in their base class. This is useful because it means you can reuse these items when appropriate for the class you are using. If the inherited member cannot be used "as is" you have the option of using the **Overrides** keyword to define a new implementation, provided that the property or method in the base class is marked with the **Overridable** keyword, or shadowing the member by redefining it in the derived class.

In practice, overridden members are often used to implement polymorphism. For more information about polymorphism see Polymorphism.

The following rules apply to overriding methods.

- You can only override members that are marked with the **Overridable** keyword in their base class.
- Properties and methods are **NotOverridable** by default.
- Overridden members must have the same arguments as the inherited members from the base class.
- The new implementation of a member can call the original implementation in the parent class by specifying **MyBase** before the method name.

Note Overloading, overriding, and shadowing are similar concepts that can be easy to confuse. See Introduction to Objects in Visual Basic for more information.

Example

Suppose you want to define classes to handle payroll. You could define a generic Payroll class that contains a RunPayroll method that calculates payroll for a normal week. You could then use Payroll as a base class for a more specialized BonusPayroll class, which could be used when distributing employee bonuses.

The BonusPayroll class can inherit, and override, the `PayEmployee` method defined in the base Payroll class**.**

The following example defines a base class, `Payroll`, and a derived class, `BonusPayroll`, which overrides an inherited method, `PayEmployee`. A procedure, `RunPayroll`, creates and then passes a `Payroll` object and a `BonusPayroll` object to a function, `Pay`, that executes the `PayEmployee` method of both objects.

```
Const BonusRate As Decimal = 1.45
Const PayRate As Decimal = 14.75

Class Payroll
   Overridable Function PayEmployee(ByVal HoursWorked As Decimal, _
         ByVal PayRate As Decimal) As Decimal
      PayEmployee = HoursWorked * PayRate
   End Function
End Class

Class BonusPayroll
   Inherits Payroll
   Overrides Function PayEmployee(ByVal HoursWorked As Decimal, _
         ByVal PayRate As Decimal) As Decimal
      ' The following code calls the original method in the base
      ' class, and then modifies the returned value.
      PayEmployee = MyBase.PayEmployee(HoursWorked, PayRate) * BonusRate
   End Function
End Class

Sub RunPayroll()
   Dim PayrollItem As Payroll = New Payroll()
   Dim BonusPayrollItem As New BonusPayroll()
   Dim HoursWorked As Decimal = 40

   MessageBox.Show("Normal pay is: " & _
   PayrollItem.PayEmployee(HoursWorked, PayRate))
   MessageBox.Show("Pay with bonus is: " & _
   BonusPayrollItem.PayEmployee(HoursWorked, PayRate))
End Sub
```

Override Modifiers

You can use the **NotOverridable** and **MustOverride** modifiers to control how properties and methods are overridden in derived classes.

The **NotOverridable** modifier defines a method of a base class that cannot be overridden in derived classes. All methods are **NotOverridable** unless marked with the **Overridable** modifier. You can use the **NotOverridable** modifier when you do not want to allow an **overridden** method to be overridden again in a derived class.

Methods defined with the **MustOverride** modifier have no implementation in the base class and must be implemented in derived classes. Classes that contain **MustOverride** methods must be marked with the **MustInherit** modifier.

Example

```
MustInherit Class BaseClass
   Public MustOverride Sub aProcedure()
End Class

Class DerivedClass
   Inherits BaseClass
   Public NotOverridable Overrides Sub aProcedure()
      ' Override a procedure inherited from the base class
      ' and mark it with the NotOverridable modifier so that
      ' it cannot be overridden in classes derived from this class.
   End Sub
End Class
```

Object Management with Collections

Collections provide an ideal way to manage a variety of objects. You can add and remove objects from a collection, retrieve them based on an index or a key, and use **For Each...Next** statements to cycle through the items in your collection. However, the very flexibility of collections can undermine the robustness of your classes.

There are three general approaches you can take to implementing object management using collections. Consider a component that organizes and exposes widgets to client components. To implement this component with collections you might:

- In the `WidgetRepository` class, declare a `Widgets` variable as a collection, and make it public.
- Implement your own `WidgetsCollection` class by inheriting from the **CollectionBase** class. Give the `WidgetRepository` class a property of the `WidgetsCollection` class.
- Implement collection-type functionality in the `WidgetRepository` class by writing the appropriate classes and methods to implement this functionality. This approach is most useful if you want to have collection-type functionality in your class, but cannot inherit from any of the collection-type classes. For example, if you wished to inherit from a class other than a collection class.

You learn how to implement the first strategy in Using Collections In Classes. The second strategy is demonstrated in Walkthrough: Creating Your Own Collection Class.

Using Collections in Classes

You can add collections to your classes to manage objects that might be exposed by that class. The simplest way of doing this is to add a public variable of type **Collection** to your class. Consider a hypothetical class called `WidgetRepository` that manages and exposes widgets. You might create a `WidgetCollection` variable to act as a collection of widgets, as shown in the following example:

```
Public Class WidgetRepository
   Public WidgetCollection As New Collection()
   ' Insert code to implement additional functionality.
End Class
```

This class now has a public collection to which Widget objects can be added. But there are a few problems with this approach. First of all, this collection is not strongly typed. What happens if the following code is executed?

```
Dim myString As String = "This is not a Widget object!"
WidgetCollection.Add(myString)
```

The answer is that it is added to the collection, even though it is not a Widget object. In fact, any object can be added to your collection, regardless of type. If you then try to use **For Each...Next** statements to process your widgets, problems ensue, as shown below:

```
Dim aWidget As Widget
For Each aWidget in WidgetCollection
   ' Insert code to process Widgets
Next
```

In the example, the program throws an **ArgumentException** exception at run time, because a member of the collection is not a Widget type.

Another problem involves exposing members of the collection. Since the **Collection** class accepts and returns members of type **Object**, you cannot use any of the functionality of the objects managed by the collection when **Option Strict** statement is **On**. To convert the reference supplied by the collection to the appropriate type, you must instead use the **CType** function, as shown below:

```
Dim myWidget As Widget
MyWidget = CType(WidgetCollection(1), Widget)
```

Note that when **Option Strict** is **Off**, the conversion is performed implicitly, though the late binding causes degradation in performance.

If you need to avoid these problems, or require a more robust type of collection for your class, you should consider using **CollectionBase** to create your own collection class. For details, see the walkthrough, Walkthrough: Creating Your Own Collection Class.

Events and Delegates

Events and delegates are closely associated in Visual Basic .NET. An event is a message sent by an object announcing that something important has happened. Events are implemented using delegates, a form of object-oriented function pointer that allows a function to be invoked indirectly by way of a reference to the function.

In This Section

Events and Event Handlers
Provides an overview of events, event handlers, and associated terminology.
Adding Events to a Class
Describes the process of defining events.
Writing Event Handlers
Demonstrates how to write event handlers using the **Handles** clause or the **AddHandler** statement.
WithEvents and the Handles Clause
Demonstrates how to use the **WithEvents** keyword and the **Handles** clause to associate an event with an event handler.
AddHandler and RemoveHandler
Demonstrates how to use the **AddHandler** and **RemoveHandler** statements to dynamically associate an event with an event handler.
Event Handler Example
Defines a class that raises an event when you call the **CauseEvent** method.
Delegates and the AddressOf Operator
Provides an introduction to delegates and how they are used.
Delegate Example
Creates a sort procedure in a class that uses the standard alphabetic sort on most list boxes, but is able to switch at run time to a custom sort procedure. To do this, you pass the custom sort procedure to the sort class at run time, using delegates.
Walkthrough: Declaring and Raising Events
Steps you through the process of declaring and raising events for a class.
Walkthrough: Handling Events
Demonstrates how to write an event handler procedure.

Event Handling in Windows Forms

Describes how to work with events associated with Windows Forms objects.

Events and Event Handlers

It is tempting to think of a Visual Studio project as a series of procedures that execute in a sequence. In reality, most programs are event driven — meaning the flow of execution is determined by external occurrences called *events*.

An event is a signal that informs an application that something important has happened. For example, when a user clicks a control on a form, the form can raise a **Click** event and call a procedure that handles the event. Events also allow separate tasks to communicate. Say, for example, that your application performs a sort task separately from the main application. If a user cancels the sort, your application can send a cancel event instructing the sort process to stop.

Event Terms and Concepts

This section describes the terms and concepts used with events in Visual Basic .NET.

Declaring Events

You declare events within classes, structures, modules, and interfaces using the **Event** keyword, as in the following example:

```
Event AnEvent(ByVal EventNumber As Integer)
```

Raising Events
